The consequences of atheroma will differ according to the size of the artery affected and the extent and nature of the affection. Atheroma of the aorta may not only weaken the coats of the vessel and give rise to the formation of aneurysm, but may affect both the heart and nerve centres in other ways. Atheromatous thickening close to the aortic orifice will tend to lessen the calibre of the coronary arteries and at the same time render them rigid and unyielding. Should an atheromatous mass undergo softening, so that an ulcer forms in the interior of the aorta, numerous granules will be discharged into the blood and will be carried to various organs and there cause embolic infarcts,[3] arresting more or less completely the circulation in the vessel beyond the part where their course is arrested. Similar consequences may

arise from atheroma of medium-sized vessels, and when very small vessels are affected their lumen may be completely obstructed by the gradual thickening of their walls, instead of by sudden arrest of the circulation by an infarct. Yet in these vessels, though the circulation has been gradually diminishing, its final arrest may be comparatively rapid, because of the formation of a thrombus at a point where the lumen of the artery has already been diminished. No organ of the body is free from the risk of vascular obstruction, but the two organs in which the symptoms are most marked and important are the heart and the brain, and the symptoms may, therefore, be divided into two great classes of cardiac and mental. All the symptoms may again be subdivided, according to their severity, into functional and organic. The term "functional" is in some respects objectionable, for it is very unlikely that any change in the function of an organ takes place without definite organic change, either physical or chemical, in the organ itself. Yet the term may be employed to indicate those slight alterations in function to which, on account of our imperfect knowledge, we are unable to assign an organic cause, but in which the cardiac disturbance is such as to indicate disordered innervation or weakness of the muscular fibre, or both conditions together. The actual weakness makes itself felt in ready exhaustion and shortness of breath on exertion, while the disordered innervation evidences itself in irregular action, discomfort or a feeling of constriction on the chest, or various degrees of pain up to the most severe. The discomfort or pain is generally increased by exercise, and consequently the patient is induced or compelled to give up the active employments or exercise to which he has been accustomed. Emotion has a similar effect to exercise, and the patient is apt to feel a great dislike to anything that calls for mental strain. The condition he suffers from is undoubtedly a complex one, for though the mental faculties are those which are called into play by emotion, yet the effect of arterial degeneration upon them is probably due to an alteration in the heart as well as the brain.

Whenever any organ is called upon for increased exertion, whether it be a muscle, a gland, or the brain itself, an increased supply of arterial blood appears to be necessary, and in a healthy organism this increased supply is always provided to the organ by dilatation of the arteries which supply it. As Bernard has well shown, the artery of a secreting gland dilates, the capillaries enlarge, and the blood gushes through them into the veins. In a contracting muscle the vessels also dilate, and although the current of blood during the actual contraction may be increased or diminished, yet the vessels of the muscles always dilate, and a full stream of blood passes through it either during the contraction itself or after the contraction is over. (Fig. 2.) A similar dilatation of the bloodvessels of the brain has been shown by Mosso, who found that even such a slight exertion as doing a sum in arithmetic would make itself evident in the circulation of the rest of the body by the withdrawal of blood to the brain in order to maintain its activity. (Fig. 3.) But when the vessels become atheromatous and rigid they can no longer dilate and supply an increased amount of blood to an organ when the necessity for it arises. The first organ to be supplied from the arterial system is the heart itself, and we find that an individual may complain of symptoms known only to himself, and which probably indicate commencing atheroma, when to all appearance he is perfectly sound and when his friends very often say they never saw him looking fitter in his life. It has seemed to me that one of the first signs is that the patients complain that they "have lost their nerve" for all ordinary work. They are perfectly fit for all ordinary occupations or businesses, for they can hunt or shoot, but when any call is made upon them for extraordinary exertion they feel themselves unequal to it. When hunting they no longer like to take a big jump, not that they feel physically unable for it, but they have a sort of indefinite fear of it, or, as they say, they "funk" it. They do not like any business question which involves sudden decision, and they may even go so far as to dislike meeting with strangers and having to talk to them on account of the extra exertion involved. Yet there may be no outward indication of all this, and the patient may be able quite successfully to conceal his feelings from everybody else. It is at present almost impossible to say how much of these feelings are really due to commencing [illegible] and rigidity of vessels and how far they may be [illegible] tissue change, and more especially by the imperfect removal of uric acid and other products of tissue waste and their consequent accumulation in the blood or organs, as mentioned by my friend Dr. Mitchell Bruce in his admirable description of the gouty heart.[a] Nor will it be easy to decide such a question, for the same treatment that would be likely to remove the uric acid and other waste products will be likely to improve the condition of the vessels and to restore the patient, at least for a time, to comparative health. If the coronary arteries are more severely implicated the effect of imperfect nutrition of the

heart itself will become still more evident, its impulse will tend to become feeble, its sounds indefinite, the pulse feeble, irregular, or intermittent, the breath shorter, and the discomfort or pain on exertion more pronounced. There may be ringing in the ears, giddiness, and occasional fits of faintness or complete loss of consciousness. Here, again, it is difficult to assign an exact cause for such nervous symptoms. One is apt to say loosely that they are "due to a little weakness of the circulation," without attempting to formulate definitely

FIG. 3.

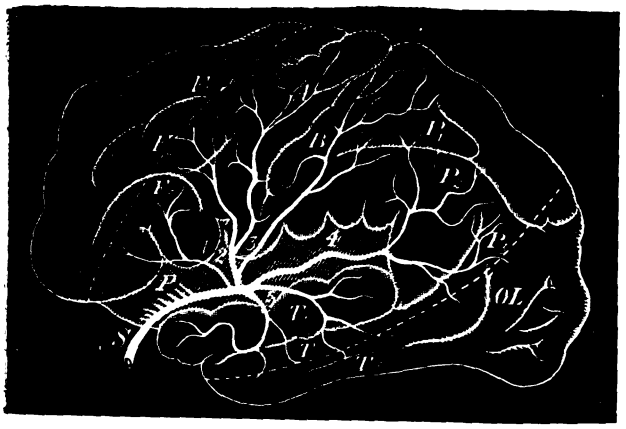
the nature of this weakness. They may possibly be sometimes due to ptomaines or leucomaines, or they may be caused by minute hæmorrhages in the nervous centres from the bursting of capillary aneurysms, but the transitory nature of the symptoms seems to indicate that frequently they are more likely due to minute embolisms than to hæmorrhages.



When we look at the excavated surface of an atheromatous

[a] Practitioner, January, 1885.

ulcer in the aorta we cannot help speculating as to where all the stuff which formerly filled it has gone, and, knowing as we do that embolisms are most likely to find a lodgment in the brain, we can hardly help trying to connect the various slight nervous symptoms which are so frequent in atheroma with the atheroma itself and with minute scattered plugs in the cerebral vessels arising from it. A glance at Fig. 4, which shows the distribution of vessels in the brain,

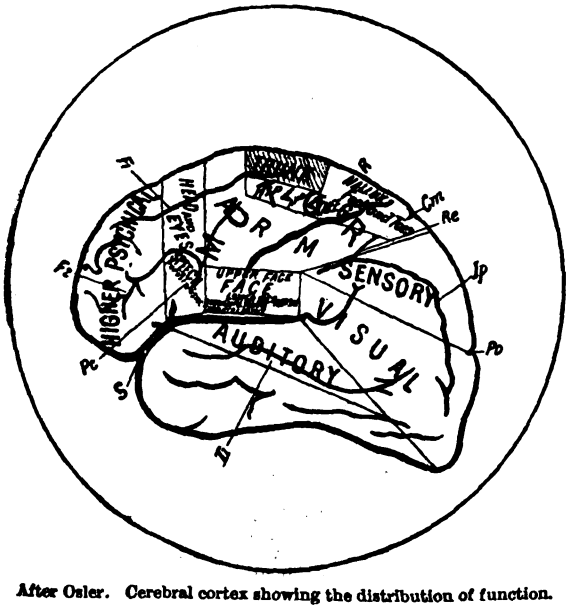

FIG. 4.

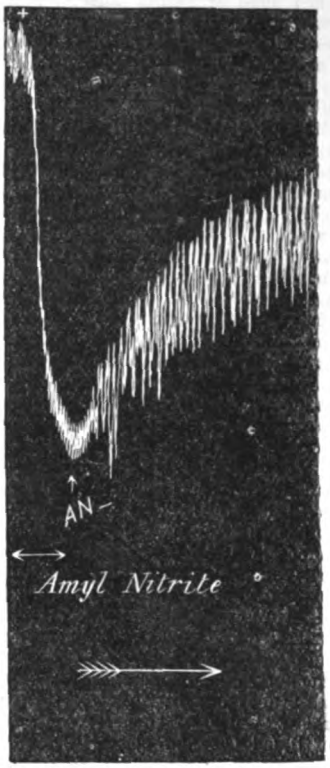
After Ross. Distribution of the arteries in the brain.

and Fig. 5, which indicates the distribution of function in the cerebral cortex, will readily show how easily minute particles, by obstructing small vessels in different parts of the brain, may give rise to symptoms of the most various sorts—sensory, motor, and intellectual. The mental symptoms may be very slight indeed, and their presence may only be ascertained when certain things have to be done. Thus, a patient of mine, a strong, very energetic man aged

FIG. 5.

After Osler. Cerebral cortex showing the distribution of function.



sixty-five, had a kind of fainting fit which left him a little stupid for a day or two. On returning to work he was perfectly well in every respect but one. He could conduct all his business, which was a large one, arrange every detail with one exception, for though he could write the correct sums and names on his cheques and sign them perfectly he could not put in the proper figures. Men with atheromatous vessels may go on for a number of years and no accident may befall them, but if the atheroma is well marked I think it is right that both they and their friends should know that the man is rather unsafe, and that he may, without much apparent warning, do a foolish thing. It is in such cases that we hear the story that "Mr. So-and-so lost his money, and this preyed so much upon his mind that he went off his head." If the case had been correctly read it would probably have been that the man had atheromatous disease, leading either to embolism or to hæmorrhage in some part of his brain, which gave rise to no motor symptoms, but so disordered his higher faculties that he committed some folly, in consequence of which he lost his fortune. The process of cerebral degeneration, of which this was the first proof, then went on until it became evident to everyone. It is strongly advisable for men aged sixty and upwards who are engaged in business and have atheromatous arteries to guard themselves against the chance of doing anything foolish, and if they are in partnership the question will arise how far the partner ought to be informed of the possibility of such an occurrence in order to safeguard his own interests as well as the patient's.

In cases of severe affection of the coronary arteries the chief risk is angina pectoris, although it is quite possible that sudden death may occur in such cases without any pain at all, and a patient may go to bed perfectly well and happy and be found dead in the morning. The pain of angina pectoris is in all probability due to weakness of the heart in proportion to the resistance it has to overcome and may be removed either by increasing the power of the heart or lessening the resistance. In most cases it is necessary to lessen the resistance in order to obtain rapid relief. This is effected by dilating the vessels by the aid of nitrite of amyl[5] or other nitrites, such as that of butyl, nitro-glycerine,[6] nitrite of soda, or hydroxylamine.[7] All these have practically the same action in causing dilatation of the arterioles. All these substances act in much the same way and dilate the peripheral arterioles so that they present less resistance to the flow of blood through them. The pressure falls, and the heart, having little resistance in front of it, is able to empty itself easily and thoroughly. This is readily seen from the tracings (Figs. 6 and 7), in which, as the pressure falls, the oscillations due to each beat of the heart become very much more marked than before. The nitrite of amyl (Fig. 6) and nitrite of iso-butyl (Fig. 7) are the quickest to act, and thus they afford relief more quickly than the others; but nitrite of soda appears to have a more prolonged action, and so does nitro-glycerine, which, being on the whole the most convenient, has become more used than any of the others. The last substance that I have tried for the relief of angina pectoris is hydrochlorate of hydroxylamine.[8] (Fig. 8.) It seems to have a more permanent action than any of the others, but it tends to irritate the stomach, and the trials I have made of it have not yet shown it to possess such advantages over the others as are likely to make it displace them, yet at the same time it is a remedy worthy of a wider trial. But all these remedies are merely palliative; they tend to avert a fatal termination, but they do not have much effect upon the vascular condition of the heart and vessels which give rise to the pain. The drug which has hitherto appeared to be most successful, not only in relieving the pain of an aneurysm, but also in averting the occurrence of spasms of angina pectoris, has been iodide of potassium in large doses of from ten to thirty grains three times a day. The beneficial effect of iodide of potassium in cases of cardiac or vascular disease due to atheroma, as well as in rheumatic affections of the joints, affords further confirmation of the likeness which Virchow has pointed out between "arteritis deformans" and "arthritis deformans." But we know only too well that in cases of arthritis deformans, more commonly known under the name of rheumatic gout, iodide of potassium may be administered in large doses until both patient and medical man are sick of the remedy and hopeless of cure. In such cases a visit to Bath, Buxton, Harrogate, or Aix may afford in a short time relief which has been sought for in vain by months of treatment at home. A course of baths, a course of water-drinking, and more especially massage of the joints, clear away the chronic thickening, remove pain, and restore flexibility to the joints. The mere use of an abundance of water as a beverage at home may, if continued for a sufficiently long

time, prove successful as a remedy. I saw a very instructive case of this a short time ago. A patient suffered from a rheumatic affection of his thumbs which rendered the metacarpo-phalangeal joints quite stiff, so that the thumbs stuck out rigidly from the hand. He went to Buxton, improved somewhat, though not greatly. After his return home he drank a pint of hot water every night and morning steadily. For months no improvement was manifested, but at the end of a year the joints became supple and are now as limber and useful as they ever were in his life. This patient's case, I think, teaches us very strongly the necessity of long-continued treatment and of not giving up in despair because no improvement is manifested even after it has been continued for months.

The kidneys are the natural emunctories of the body, and through them the products of tissue waste ought to be eliminated. But some of these products, such as uric acid and urate of soda, are very sparingly soluble, and if little water be drunk they may remain embedded in the tissues instead of being eliminated. Many patients, and especially those having a gouty tendency, hardly ever touch water pure and simple. They may take a little in the form of soup, tea, or coffee, but their chief drink

FIG. 8.

Action of hydroxylamine hydrochlorate on blood pressure.

with their meals is wine, and between meals they do not drink at all. In the treatment of atheroma, then, as well as of rheumatic joints, I regard the administration of hot water as a most useful agent, and one which ought to be continued for months or years together. But when we look at an atheromatous artery the condition seems quite as unpromising and as unlikely or even more unlikely to yield to treatment than that of a deformed joint. It is quite natural that one should be sceptical as to the advantages to be derived from the use of hot water in either the one or the other, yet the case of the man I have just mentioned may make us hopeful in regard to atheroma as well as to arthritis. His cure was, however, a very slow one, and not to be compared in rapidity with those which are of everyday occurrence at Bath and Aix. There can be little or no doubt that at these places the use of massage in affections of the joints greatly contributes to the rapidity of the cure. Is it possible, then, to exercise anything like massage upon the heart and vessels? Before answering this question it may be well to consider what massage really is. Under the name are included kneading, stroking, and tapping with various degrees of force. The main object of the procedure is to imitate artificially the arrangement which exists naturally in all organs of the body for getting rid of waste products from the organs in which they are produced, and for increasing the supply of fresh

Digitized by Google

blood to these organs. As Claude Bernard has well put it, all the cells of which our bodies are composed live in a liquid medium—viz., the tissue juice in which they are all bathed. This tissue juice fills up the interstices between the cells. It derives fresh nutriment and oxygen from the blood in the capillaries. These it yields up to the tissues and receives from them in return their waste products, which it sends out partly through the veins and partly through the lymphatics. In some cases the lymph spaces appear to communicate directly with the lymphatics, while in others they appear to communicate only indirectly, no definite opening being visible through which the tissue juice can flow into the lymphatics, but yet it may pass readily into them even although it has to traverse endothelial cells. The effect of alternate pressure on a flow of lymph has been made a special study by Ludwig and his scholars. Muscular exercise, for example, is found greatly to increase the flow of lymph, and the mechanism by which this is effected appears to be the following. Each muscle is surrounded by a strong fascia consisting of two layers. Between each there exists a lymph space. When a muscle is relaxed and elongated its transverse diameter becomes less—or, in other words, it shrinks away from its sheath and thus tends to drag the internal layer away from the outer. (Fig. 9, A.) It thus

FIG. 9.

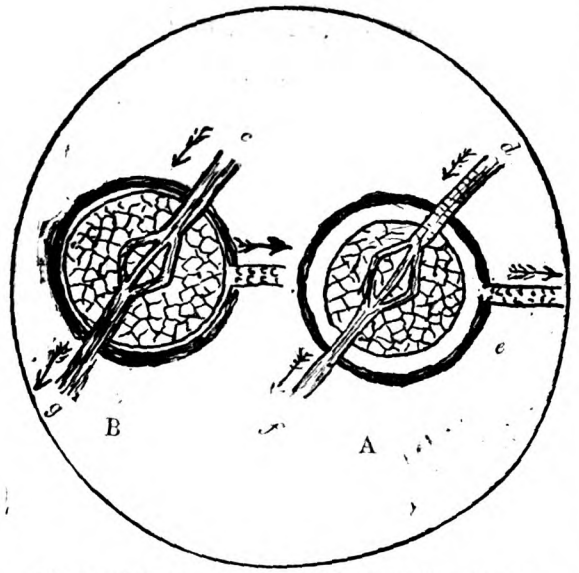

Diagram of transverse section of voluntary muscle to show the pumping action exerted on the muscle, juice and waste products during action. The bloodvessels cross diagonally. To the left (B) the muscle is contracted and presses the two layers of the fascia together so as to drive the muscle juice out into the lymphatics. To the right (A) the muscle is relaxed and tends to draw the layers of fascia apart and suck the juice out of the muscle into the lymph space. *c*, Artery. *d*, Artery. *e*, Lymphatics. *f*, Vein. *g*, Vein.

tends to create a vacuum between the two layers of the fascia, and into this the tissue juice of the muscle is drawn. When a muscle again contracts and shortens it becomes at the same time thicker, and pushes the internal layer of the fascia against the external. (Fig. 9, B.) The fluid is thus driven out of the lymph space onwards into the lymphatics, and its return is prevented by the numerous valves with which these lymphatics are furnished. Each time that a muscle contracts it drives the fluid onwards; each time that it relaxes it sucks its tissue juice and products of waste into the lymph spaces, and thus the more it acts, up to a certain point, the more thoroughly are its waste products eliminated. The result of such action is well seen in an old cab horse on a frosty morning. For the first half-mile or so the poor creature seems as if it could hardly put one foot before the other, then its pace quickens, and after it has gone some distance its legs are supple and its pace is rapid. A similar condition is noticed in muscular rheumatism in man, where the slightest movement causes pain at first; but, after a little exercise, the waste products being pumped out, the muscle recovers its normal condition, the pain is eased, and its function becomes normal. At the same time that the action of the muscle thus pumps away its waste products, provision is made for a fresh supply of nutriment, and as the muscle contracts its arteries dilate and a free flow of blood occurs through them. Sometimes the mechanical obstruction presented to the flow of blood by the contracting muscle may retard the circulation during the actual contraction, but after it is over the circulation through the muscle is greatly increased. (Fig. 2.) In glands the increased flow of blood in itself and the dilatation of the vessels in the gland will tend to press out the lymph, for the gland is almost always enclosed in a firm fibrous capsule.

The peritoneum, pleura, and pericardium are all lymph spaces, and the manner in which fluid is absorbed from the peritoneal cavity by the central tendon of the diaphragm and from the thorax by the costal pleura has been beautifully shown by Ludwig and his scholars, although von Recklinghausen was the first to observe the absorptive power of the diaphragm. The more the diaphragm acts the more quickly is fluid absorbed by it from the peritoneal cavity, and the more the thoracic walls act the more quickly is liquid pumped from the pleural cavity. The mere act of respiration tends to pump out the lymph from the peritoneum and pleura, and thus to maintain perfect nutrition in these important cavities. In the pericardium a pumping action is

FIG. 10.

Diagram of a transverse section of the thorax during inspiration and cardiac systole. It shows the tendency to the formation of a vacuum in the pleural and pericardial cavities.

kept up both by the respiration and by the pulsations of the heart itself. We may understand this more easily if we look at the diagrams of Figs. 10 and 11. In Fig. 10 I have tried to represent the condition of inspiration and cardiac systole. In inspiration the chest walls expand and tend to cause a cavity between the two layers of the pleura. The suction action which they thus exert is evident, not only from the entrance of air into the lung through the normal air passages, but from the way in which air will rush in when any opening has been made into the thorax between the ribs. This suction action is not only exerted upon the lungs, but upon the pericardium, which it tends to withdraw from the heart. If at the same time the heart is contracting it tends to create a cavity in the pericardium, and thus suction is exerted upon the pericardium and upon the heart itself, which will not only tend to draw fluid into the pericardial space, but also fresh tissue juice into the substance of the heart. In Fig. 11 I have tried to represent very diagrammatically the condition during expiration and during cardiac diastole. The chest wall, sinking down upon the distended lung, will tend to press any fluid in the pleural cavity into the lymphatics of the chest wall and will also tend, along with the diastolic expansion of the heart, to press fluid out of the pericardium into its lymphatics, and out of the muscular substance of the heart into its lymphatic

Digitized by Google

vessels. In this way we can see that the movements of respiration, as well as those of the heart itself, constitute a kind of massage to the lungs, thoracic walls, pericardium, and heart—a fact which was clearly pointed out some years ago by my friend, Professor Hugo Kronecker. Nor is this all,

FIG. 11

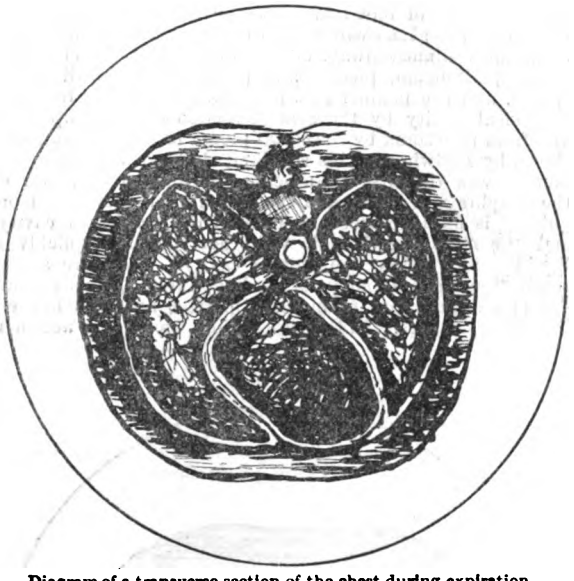

Diagram of a transverse section of the chest during expiration and cardiac diastole, showing the pressure of the walls of the pleural and pericardial cavities against each other.

for the walls of the arteries are themselves likewise subject to a kind of massage by the alternate systole and diastole of the heart (Fig. 12), and this fact is of great importance. Between the intima and media, and probably in the media itself, there are lymphatic spaces, and in the adventitia there are distinct lymphatic vessels. Encased, as many of the

FIG. 12.

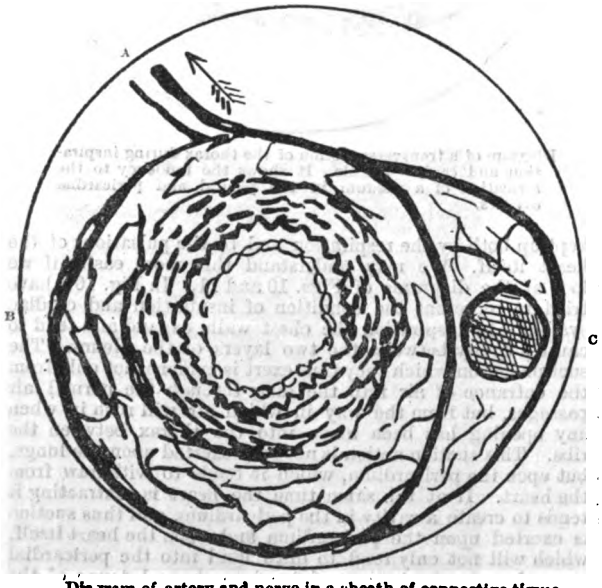

Diagram of artery and nerve in a sheath of connective tissue. A, Lymphatics. B, Sheath. C, Nerve.

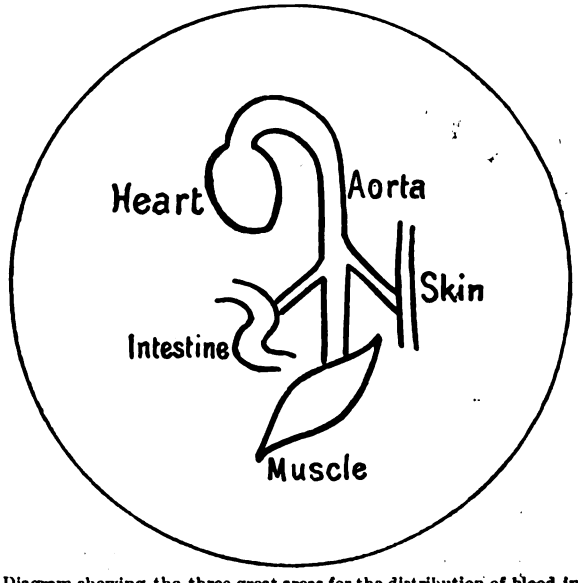
arteries are, in a strong fibrous sheath, their alternate distension and relaxation at each pulsation will tend alternately to drive the internal layer against the middle and the middle against the outer, so that any fluid lying between them will be driven onwards into the lymphatics with each systole of the heart, and during the diastole the arterial coats will tend to separate from one another and thus draw in fresh supplies of tissue juice from the vasa vasorum. The mechanism by which the nutrition of the arteries is maintained is thus seen to be very much like that of the muscles. In some animals, instead of there being merely lymph spaces or small lymphatic vessels between the artery and its coat, a regular lymphatic vessel is seen to surround the artery, which forms, as it were, the core of the lymphatic. This condition is seen in the aorta of the tortoise, and it occurs also in the vessels of the brain. Nor is the utility of the massage action exercised by the alternate dilatation and contraction of the artery confined to the nutrition of the artery itself, for not infrequently we find that a nerve trunk—e.g., the vagus—runs along with the artery enclosed in a common sheath of unyielding connective tissue. The contraction and dilatation of the vessel will exert a kind of massage upon the accompanying nerve, similar to its action on the arterial walls, and will thus tend to maintain the nutrition of the nerve as well as of the artery.

It is well known that without exercise we cannot have the muscles in first-rate order, and the same thing is universally acknowledged in regard to the heart. No athlete would think of running a race without previous training—a training which is even more necessary for his circulation and consequent wind and endurance than for the muscles of his limbs. It is obvious that if the respirations be shallow and few, and if the beats of the heart be feeble and imperfect, the thoracic organs, and more especially the heart and arteries,

FIG. 13.



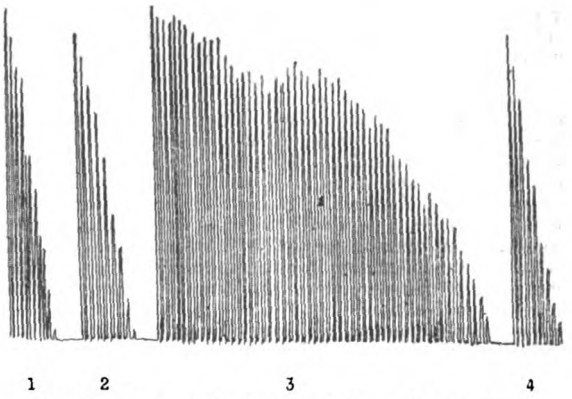


Diagram showing the three great areas for the distribution of blood in the body—viz., the muscles, the intestine, and the skin.

will suffer in their nutrition. The removal of waste from them will be less perfect, and they will be liable, not only to the accumulation of such forms of tissue waste as will render them functionally feeble or irritable, but also to the distinct organic changes which we know as atheroma. Feeble action of the heart, although in some respects it may be a safeguard against rupture of weak or brittle arteries, is in itself a distinct evil, as lessening the nutrition both of the organ itself, of the arteries which convey the blood, and of the tissues which they should nourish. How, then, is the nutrition of the heart to be improved and its power increased? As I have already said, if the difference between systole and diastole is great, the removal of waste products will be more perfect, and this difference may be increased by causing the circulation to become more rapid, lessening the resistance in the arteries so that they present no obstruction to the heart's emptying itself, and allowing the blood to pour rapidly through the venous system back into the heart so that it is thoroughly filled during diastole. There are three large systems, or vascular districts as we may term them, in the body. The first is the skin, the second the intestines, and the third the muscles. (Fig. 13.) It is exceedingly curious to note how little

Digitized by Google

the enormous vascular district of the muscles is taken into account even in recent works on physiology, and how all the variations in blood pressure are referred to contraction of vessels either in the skin or in the intestines. And yet the vessels of the muscles are as important as both the other two taken together. When the vessels of the muscles dilate during exercise they allow the blood to flow rapidly through, but during the muscular contractions the flow may first be interrupted mechanically, and the general blood pressure may rise. (Cf. Fig. 2.) This rise, slight though it may be, is sufficient in some cases of weak heart to produce intense pain and danger, so that a man suffering from angina pectoris is obliged to desist from attempting to walk up even a slight incline. Yet if he can continue the muscular exercise the pain passes off and he gets freedom of action resembling that commonly known as "second wind," a condition which is probably also connected with the circulation through the muscle. In such cases some good results on the circulation may be obtained without any risk by substituting massage of the muscles for actual exercise. My friend Dr. Tunnicliffe and I have made some experiments on the effect of massage on muscles. The effect of massage upon muscle is simply to imitate artificially the process by which waste products are naturally removed from it. Instead of the muscle contracting and driving on its tissue juice containing the waste products into the lymphatics by pressing the inner layer of the fascia against the outer, the muscle is kneaded so as to express its juice, and this is then rubbed onwards into the lymphatics by upward pressure and stroking. The kneading and stroking are the two most efficient movements in massage, but they may be assisted by tapping with more or less force, for this movement appears to excite reflexly an increased circulation both in the skin and in the muscles themselves. By means of these three movements combined the waste products are readily removed from the muscle, while at the same time no fresh ones are produced by

FIG. 14.

renewed muscular contractions, as they are in ordinary exercise. The flow of blood through a muscle is enormously accelerated, and its contractile power correspondingly increased. Even when a muscle has been so much fatigued

FIG. 15.

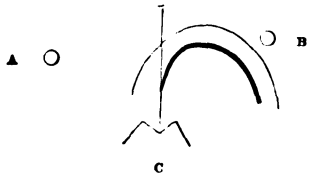
Digitized by Google

that it can hardly contract any more its contractile power is restored by massage, as is evident from the tracings (Fig. 14). These are made by bending the finger with a weight attached to it until it is so exhausted as to be unable to contract any more. The movements are recorded by a point upon a blackened cylinder. From the tracings it is evident that a few minutes' massage increases the power and endurance of exhausted muscles up to or even beyond their normal. On comparing the effect of massage of muscles on the circulation through them, as observed by Dr. Tunnicliffe and myself, with the results obtained by Ludwig and Sadler after stimulation of the motor nerves of muscles, it will be found that they are very similar. The effect of massage when seen in actual experiments is even more striking than as it appears in the diagrams. To say that the flow of blood through a muscle is increased threefold by massage means a good deal, but it hardly suggests to one the tremendous gush with which the blood does flow through the muscle (Fig. 15). By the use of massage, then, the circulation is quickened, the resistance is diminished (Fig. 16), the filling of the blood during diastole increased, and thus the pumping of waste products out of the heart itself is more thoroughly effected. At the same time there can be little doubt that a similar increase of blood-supply to the heart itself takes place even if the coronary arteries are contracted; and as it is called upon to make no extra exertion, but, on the contrary, to work against less pressure than before, we may expect it to become better nourished and better able for the work. But simple massage will not increase the thoracic movements, and these, as I have mentioned, are important adjuncts. Therefore it is that, if the patient be strong enough, carefully graduated movements may be added to massage or replace it entirely. For these movements will increase the flow of blood through the muscles and have all the other useful actions I have mentioned as resulting from massage. Massage in the treatment of heart disease is, I believe, first mentioned by Harvey, but its employment was first reduced to a system in Sweden by Ling and others. The Swedish cure attracted but little attention in this country or on the Continent until the system of treatment by baths and movements was taken up by the brothers Schott of Nauheim, and the great success which has attended the use of this method seems likely to lead to its general adoption and recognition. The method consists chiefly in the use of graduated movements, which are made at first against very slight resistance, the resistance being increased as the patient is able to bear it, until at last the patient may be obliged to use a considerable amount of muscular effort. Under this treatment dilated hearts become rapidly smaller, at least up to a certain point, as is shown by the accompanying figure (Fig. 17), which I owe to the kindness of

FIG. 17.



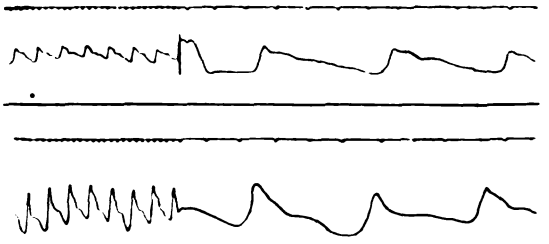


Diagram of the cardiac dulness before and after a bath. A similar effect is produced by gymnastic exercises. The thin line shows the graduated dulness before and the thick one after. A, Nipple. B, Nipple. C, Ensiform cartilage.

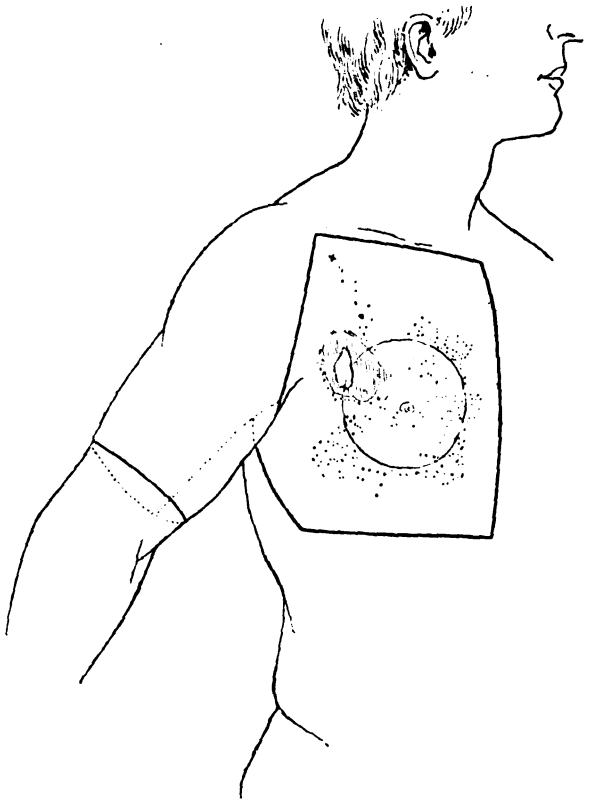
Dr. Schott. But it is evident that the alternate expansion and contraction of the arteries may be very slight, and their self-massage, as we may term it, very imperfect if the arterial tension be high, as we often find in gouty patients, even although the heart may be strong. Can anything be done to remedy this condition permanently? I believe it can. I have only begun to use the treatment, and I can only give you at present one example; but from it you will see that a systematic course of exercises has brought about in the case of a gouty man the precise alteration in the pulse for which we would seek—a diminution in the resistance and a more powerful action of the heart (Fig. 18)—so that instead of a pulse tracing with a slow ascent, indicating feebleness of the heart, in proportion to the resistance, and a slow descent, indicating contracted arterioles, we get a rapid and much larger ascent, indicating increased contractile power of the heart, and a quicker fall, showing less resistance in the arteries. Such a case as this makes one hopeful that, unpromising as arteritis deformans is in regard to treatment, we may yet have such power to cure it as we have in the case of arthritis deformans. I should not have ventured to bring before you a plan of treatment based upon one case alone were it not that this, although the only one that I have, is simply one of many that have been recorded. Nor does it seem much to claim for the plan of treatment, for it is a fact that many, perhaps most, people in civilised countries either cannot or will not take enough exercise, or exercise of the right sort, and it is an exceedingly common thing to hear a man's friends remark that if he would take more exercise he would be perfectly well. But a mere walk along the flat cannot be regarded as exercise for many people. It may be all that they are able to take on account of the weakness of their muscles or the flabbiness of their heart, but it is insufficient to produce the cardiac, vascular, and

FIG. 18.

Pulse tracing showing the effect of massage and graduated movements. Each tracing is taken partly with a slow and partly with a quick movement of the sphygmograph. The upper shows high tension and a feeble heart; the lower shows less tension and a stronger heart. These tracings I owe to the kindness of Dr. Gustav Hamel, to whose treatment I had recommended the patient.

respiratory self-massage of which I have spoken, and if the patient tries to do more he may overstrain himself and do more harm than good. The whole essence of the treatment which I have been advising for atheroma and its consequences may be shortly summed up in a few words—namely, water drinking and graduated exercise, passive and active. Simple as these remedies are, they are, I believe, the most potent of all in improving, or even, perhaps, removing completely, a condition which is of the utmost gravity from its relation both to the heart and the brain. It is, indeed, natural to expect that they should be powerful curative agents, for they are neither more nor less than the means by which Nature itself keeps up the healthy nutrition of every organ in the body, where the utmost pains seem to have been expended upon mechanisms whereby not only fresh nutriment should be supplied, but waste products should be removed with greater or less speed, according to the greater or less functional activity of each organ.

A CASE ILLUSTRATING A VERY EFFECTUAL METHOD OF TREATING EXTENSIVE MALIGNANT DISEASE OF THE BREAST.



BY W. ARBUTHNOT LANE, M.S., F.R.C.S. ENG.,
ASSISTANT SURGEON TO GUY'S HOSPITAL AND TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

THERE are many cases of extensive cancer of the breast and of the superjacent surrounding skin, associated with infection of the axillary glands and possibly also of those in the subclavian triangle, in which the surgeon must feel that if he could make a clean sweep of the whole disease he would be able to offer his patient a fair chance of subsequent freedom from recurrence, and in the immediate future much certain relief from pain and mental distress. The great difficulty he has to meet is the covering of a large and raw square surface whose sides may vary in length between eight and twelve inches. He also recognises the risks of septic infection associated with such a large wound, its painful and tedious nature, and the fact that even if he succeeds in grafting such a large area the resulting scar is necessarily a

Digitized by Google

most unsatisfactory one. Since I adopted the operative measures described in the Clinical Society's Transactions,[1] in a paper entitled "A more efficient Mode of treating Cancer of the Breast"—namely, removing the pectorals, carefully dissecting away every particle of glandular and areolar tissue from the axilla, and also, if necessary, dividing the clavicle and clearing out the subclavian triangle—I have found myself very well repaid for the extra time and trouble such an operation demands, and the very slight added risk from hæmorrhage and a certain limitation of movement resulting from the removal of the pectorals more than compensated for by the subsequent increased duration of the patient's life. One comes across cases, however, in which the skin is so extensively infected that this last operation is unsatisfactory owing to the large raw surface which is necessarily left. In such cases I would urge what at first sight appears to be a heroic measure—namely, amputation of the arm at the shoulder in order to obtain enough skin to cover the raw surface and to give a nice soft covering to the part. The patient will certainly die if she is not operated on, and in all human probability the arm will shortly become a source of distress to the sufferer owing to interference with the venous channels; therefore, it is no great deprivation to remove it. Besides, it diminishes the risk of the operation, it ensures immediate union, and within a very few days the patient is enabled to get about and enjoy an active existence. Perhaps I cannot do better than illustrate the method I here advocate by means of the report of a case.

A woman aged twenty-nine years, single, of a remarkably youthful appearance, was admitted under my care into Guy's Hospital on Sept. 9th, 1895, suffering from carcinoma of the right breast, which she had observed for the first time five months before. The mass was large and involved almost the entire breast. The skin was adherent over it and was ulcerated over a space as large as a five-shilling piece. All about the ulcer and for an area around the breast the skin presented minute nodules of infection. There were enlarged glands in the axilla, and in the subcutaneous tissue over the coracoid process a gland could be felt. It had apparently been infected from some cutaneous nodules just below it. Nothing could be felt in the liver, and the patient's general health and weight were as good as ever they were. The advantage of removing the arm, the possible benefit she would derive from it, and the risks she ran were fully explained to her, and she insisted on undergoing the operation. An incision was made along the length of the clavicle to the middle line, and the middle third or more of the clavicle was exposed and removed. The subclavian artery and vein were tied at the margin of the scalenus anticus, and all the areolar tissue and glands in the subclavian triangle carefully dissected out. There was no obvious infection of these glands, but beneath the clavicle the upper limit of the enlarged axillary glands was defined and the glands were turned downwards. Great care was taken not to injure the supra-scapular or other vessels crossing the subclavian triangle. From the inner limit of the horizontal incision another was carried down vertically along the middle line for about nine inches. It lay well outside the limit of skin infection. From its lower end another incision was carried backwards to the posterior fold of the axilla at what seemed a safe distance from the growth, and then it was run upwards along the posterior fold to the axilla, when it ran across the arm to the outer end of the clavicle. A vertical incision was made from the upper limit of the posterior axillary fold to the elbow, where it was crossed by a circular incision. The skin and subcutaneous tissue were dissected up off the deep fascia as far as the deltoid, out of which a large and sufficient flap was cut to ensure as much vascularity of the flap as possible. The inner part of the deltoid was removed and the limb disarticulated. The skin and all the subjacent soft parts were dissected off the sternum, clavicle, ribs, cartilages, intercostal muscles, serratus magnus, and posterior wall of the axilla, and the great square flap, which measured more than nine inches along each side, was fitted accurately and comfortably into the large exposed raw area. The part that corresponded to the circular incision around the arm was united to the edge of the median or sternal incision, while the edges of the vertical incision in the arm were connected to the upper and lower horizontal incisions in the thorax. Very little blood was lost during the operation. The growth was found to involve the greater pectoral, but the most careful subsequent examination of the parts excised showed that the primary growth, the skin, and glands were very freely removed. The patient ran the usual course of an aseptic wound, experiencing no discomfort or pain in the part. The illustration represents diagrammatically the condition of

The above illustration shows the positions of the incisions, with the ulcerated surface in the right and upper part of the breast. The cross indicates the position of the gland in the subcutaneous tissue, and the dots show the approximate distribution of the points of infection of the skin by growth.

the patient before the operation, and it shows very well the outline of the skin incisions in the chest and arm. Of course, the area of the surface covered by the skin of the arm after healing had taken place was considerably smaller than when the operation was done, owing to a certain amount of shrinkage of the loose flap.

I would just point out that the removal of a considerable portion of the clavicle enabled me not only to remove all glandular and areolar tissue beneath and about it and to tie the vessels securely and with a minimum loss of time, but it also allowed the scapula to fall into such a position as to give a greater length of flap and a less strain upon it than if the clavicle were left intact. Every operating surgeon of large experience is confronted too often with the results of very imperfect removal of the diseased structures, so much so that he sometimes cannot but think that the operator was influenced by a desire not so much to effect the thorough removal of the affected parts as to obtain a rapid recovery. It would seem obvious that such a course is not likely to reflect much credit on surgeons, and especially on operations for cancer of the breast.

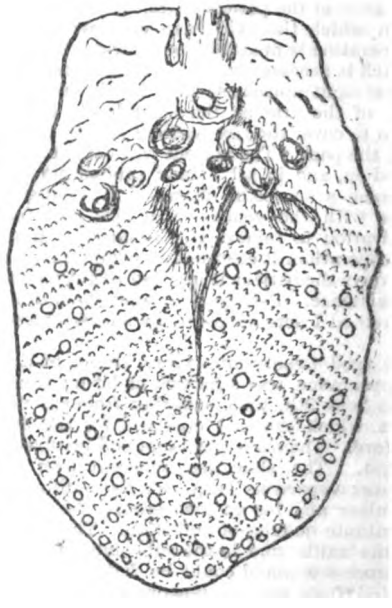
SORE-THROATS IN INFLUENZA; THE TONGUE AS AN AID TO DIAGNOSIS; THE DIFFICULTIES OF DIFFERENTIAL DIAGNOSIS.

BY JOHN TERRY, M.R.C.S. ENG., L.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, ROYAL SURREY COUNTY HOSPITAL, GUILDFORD.

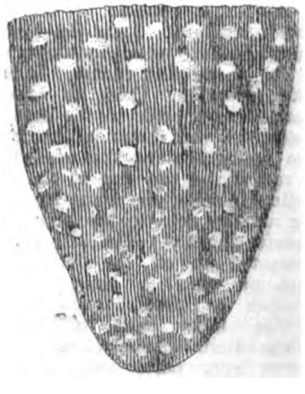
SOME months ago a letter of mine on "Sore-throats in Influenza" was published in THE LANCET.[1] The epidemic was then at its height, and I made a few remarks on the condition of the tonsils, uvula, pharynx, larynx, and tongue. In answer to some questions I asked I received numerous replies, most of them verifying my notes in every detail, and I wish especially to thank Dr. G. B. Barron, Mr. J. H. Caird, Mr. P. M. Davidson, Dr. E. J. McC. Morris, and others for their courtesy. Since then I have studied carefully a great many cases, both in the acute febrile stage and in a sort of subacute and chronic stage. I should now like to say a few words on the condition of the tongue in each of these stages, as I feel certain that if any of the conditions to be described are present in any case we may safely diagnose influenza, whatever else there may be in addition. The symptoms such as headache, feverishness, and pains in the back and limbs are so well known that of them I shall say nothing. Everyone must have known how difficult it is sometimes to diagnose for certain an ordinary case of influenza even during a recognised epidemic; it is more especially difficult to do so when the case occurs previously to or at the end of a general outbreak. True it is that the blood or sputum may be examined for the influenza bacillus; but it is not absolutely certain that the specific bacillus has been found, and even if it is granted that the bacillus described by Pfeiffer and Kitasato is the true influenza bacillus it is not everyone who has the time or the means at his disposal to make a bacteriological examination. If the condition of the tongue immediately to be described is fairly constant, and I believe it is, I think we have an important aid to the diagnosis of influenza. In the early acute stage of the disease the tongue is covered as a rule with whitish or greyish fur; this layer may be so thin that the pink substance of the tongue shows through it; or it may be absent, the tongue being clean, but often fissured. The characteristic feature, however, is the presence of dark purplish-red spots or elevations scattered all over the tongue, being most

FIG. 1.



numerous on the anterior half of the dorsum and on the tip and edges; they are rather larger than an ordinary pin's head and are probably enlarged fungiform papillæ. At the back of the tongue, in the region of the circumvallate papillæ, there are several largish elevations varying in size from that of a pin's head to a split pea or even larger; they are fleshy in colour and somewhat resemble mucous condylomata. (Figs. 1 and 2.) When the tongue is coated with white fur the red elevated papillæ produce an appearance most characteristic—a white strawberry tongue; when there is no fur the appearance is more like a red strawberry.

[1] THE LANCET, March 9th, 1895.



At a rather later stage the red spots or elevations have turned into pinkish-white jelly-like vesicles; on pricking them, however, no fluid escapes. In the chronic cases—i.e., those cases in which the patients have got over the acute febrile stage, but are still weak and ill, or those where there has been a relapse (which often occurs if the patient resumes his work too soon)—the tongue still shows quite characteristic signs; it is generally of a deep-red or purplish colour, is fairly clean or is sometimes slightly covered with a greyish or brownish

FIG. 2.

fur; the purple spots or pinkish-white jelly-like vesicles are no longer to be seen, their place being occupied by translucent white vesicles which are rather larger than those of the earlier stages. The elevations on the posterior third of the tongue are now white or greyish-white in colour. (Figs. 2 and 3.) I must point out that the order of the changes in the tongue as here described is not constant; the purplish spots may remain spots all through, or the jelly-like vesicles may persist throughout, and so on, but in a majority of cases the description holds good. In every case of influenza, however, one or

FIG. 3.

other of the conditions of the tongue is present. Besides these changes in the tongue, small whitish vesicles may be seen on the mucous membrane of the lips, cheeks, hard and soft palate, and on the pharynx; on the palate and pharynx they are sometimes much elongated and then look like small slugs; this latter condition, however, is not common. The throat is usually found to be dry and red, the pharynx is much congested and sometimes slightly ulcerated, and the veins on it stand out prominently, often presenting little varicosities. In the late stages the tonsils may

Digitized by Google

still be enlarged and red, but tonsillitis, which is often markedly follicular in the earlier stages, is now much less frequent; often, indeed, the tonsils and uvula have shrivelled up to very small dimensions. As the patient gets better the spots or vesicles become less and less pronounced, and finally, when he is well, completely disappear. The spots may, as before said, last some weeks, although the patient expresses himself as feeling quite well, but I do not consider that the influenza has departed until the tongue is quite clear.

I shall not here describe any of the sequelæ or usual complications of influenza, as they are so fully gone into in the various excellent books and pamphlets which have of late been written on this subject. But I must draw attention to one complication which I believe is not at all infrequent and yet, as far as I can ascertain, has not been heretofore described, at least in connexion with influenza. I refer to the development of a "membrane" on various mucous surfaces of the mouth and throat; any part may become affected, but the chief sites are on one or both tonsils, the uvula, the hard or soft palate, and on the pharynx or even the larynx. This "membrane" may be either diphtheritic or non-diphtheritic. Whichever it is, the micro-organism finds the congested or ulcerated mucous membrane caused by influenza a suitable soil for its further growth and development. The "membrane" formed in either case is physically almost the same; and the importance of recognising that the diphtheria bacillus is not the only one that can lodge in the mouth or throat and form a "membrane" there is enormous. Within the last fifteen months I have had under my care some forty-five cases with a "membrane" on some part of the throat or mouth; to look at, they resembled exactly cases of diphtheria, but beyond the "membrane" there was no other sign or symptom of it. In nearly all the cases the symptoms resembled a sharp attack of influenza with complications, but there was no rapid exhaustion with quick feeble pulse, no albuminuria, and no post-paralysis, and with proper treatment the patients got quite well in from about one to three or four weeks. The "membrane" after being pulled off or coughed up in no case returned, a superficial ulcer being left, which, although painful on swallowing or gargling, healed up rapidly. I may add that nearly every one of these cases presented what I have called "the influenza tongue." It may be urged that a bacteriological examination will settle the question; this, as matters are now, I very much doubt. On several occasions I have sent specimens of "membrane" and discharges from the throat to London to be examined. One case only of these was undoubted diphtheria, for there were rapid exhaustion, a quick, feeble pulse, albuminuria, and post-paralysis; but no diphtheria bacilli were found, although the membrane sent up to be examined was a large fresh piece untouched by medicines, gargles, or paints. Other cases—some apparently of ordinary follicular tonsillitis, and some of ulcerated tonsils without membrane and others with, but with no other sign of diphtheria—were said to be "swarming with the diphtheria bacillus." I believe the fallacy of examination is due to the fact that inoculation on animals is seldom done because of its expense, the time required, or the difficulty in obtaining a vivisection licence; hence one has to rely upon the appearance of the colonies and upon the microscopical examination of the bacilli found therein; surely this must be almost useless. One report says: "There is a good deal of irregular growth present, but not characteristic of diphtheria"; and the microscope showed "the presence of numbers of a short, thick bacillus closely resembling the 'short variety' of the bacillus diphtheriæ." Another states: "It is quite possible that the bacilli may be the 'pseudo-diphtheritic bacilli.'" In a third case (that of a man aged thirty years whose hard and soft palate, both tonsils, uvula, and pharynx were covered with patches of thick, white membrane, and which was diagnosed by several medical men as diphtheria) the report was: "Unable to detect any bacillus diphtheriæ either in the membrane, on the cotton-wool, or in the culture tube." In another case in which the patient got perfectly well in a week the report was: "The culture shows numerous whitish-grey colonies of growth very characteristic of diphtheria; the culture shows also certain other colonies"; and by the microscope were seen "first, the bacillus diphtheriæ of 'medium length'; secondly, groups of staphylococci." I quote these reports, not in any way doubting that the true diphtheria bacillus has been found, but to show that examination by culture and by the microscope without other confirmatory tests—e.g., inoculation—is almost if not quite useless, or at any rate very misleading.

In conclusion I wish to lay stress on the following points. 1. That the condition of tongue as described is an almost infallible sign of influenza and that there must be very few cases in which, in one form or other, it does not occur. Although in the last fifteen months I have seen over 1500 cases, I have not met one which did not show some of the appearances described. 2. That however simple a case of influenza may appear to be, it must be treated with great care, especially with regard to the purity of the air; for in crowded hospitals or in badly ventilated houses or in houses connected with or near bad drains or cesspools the congested or ulcerated mucous membrane of the mouth or throat may easily take up one or more of the numerous micro-organisms, causing follicular or simple tonsillitis, simple membranous inflammation, or diphtheria, as the case may be. 3. That the simple (non-diphtheritic) membranous inflammation, although having nothing in common with diphtheria, is highly infectious; and, though as a rule admitting of easy cure, in weakly adults or in children the disease may be extremely serious or even fatal. Since writing the above I have read an article in THE LANCET[2] by Dr. Thresh; I can corroborate fully nearly all his statements, and with him I agree that it is high time that we adopted some other name for those cases of membranous inflammation which are without any doubt, in my opinion, not diphtheria.

Guildford.

THREE CASES OF PAROSMIA; CAUSES, TREATMENT, &c.

BY HERBERT TILLEY, M.D. LOND.,
ASSISTANT SURGEON, LONDON EAR AND THROAT HOSPITAL.

SUBJECTIVE sensations of smell of sufficient intensity to cause the patient to seek medical relief for the symptom alone being a comparatively rare disorder where the mental and general conditions are otherwise normal, the following three cases which have recently come under my notice may be of interest. The main features in all of them are the intensity of the unpleasant sensation and the absence in the nasal cavities of any visible pathological lesion.

CASE 1.—A man aged thirty-eight years came to me on May 6th, 1895, complaining of a "strong smell of ammonia," which he first noticed on recovering from a severe attack of influenza last February. The symptoms continued with varying intensity till May, and during that time he had been treated with nerve tonics and changes of air and surroundings, but without any effect. The unpleasant sensation was so strong that he left his business and avoided all his friends, as he was sure they were inconvenienced by it. He had never had any nasal trouble. Examination showed the nasal cavities to be perfectly healthy in every respect. I prescribed nerve tonics for him for a fortnight, but without any result, and then ordered him to use a solution of strychnia (ten mimims to one drachm daily) as an intra-nasal spray. This proved permanently efficient in the course of a week.

CASE 2.—A man aged thirty-six years applied to me at the London Ear and Throat Hospital, complaining of a smell of "tallow candles" in his nose which had lasted eighteen months. He could not account for its presence, as he was otherwise in perfect health. He is one of a number of shop assistants, and, although none of his companions have ever complained of him, yet he is sure they notice the smell and avoid him. On examination the nasal cavities were found to be perfectly healthy and his breath in no way offensive. The treatment was similar to that employed in Case 1, but the relief was not complete, nor was it made so by the exhibition of stimulant snuffs and lotions.

CASE 3.—A woman aged forty-six years applied to me in June, 1895, on account of a "foul smell" in the nose, which led her to give up a valuable situation. Her medical attendant had treated her for "ozena," and a rhinologist had told her that her symptoms were due to "decayed bone in the nose." The trouble had been going on for twelve months and latterly getting worse. As in the preceding cases, no one had ever mentioned an offensive smell as accompanying

[2] THE LANCET, Aug. 17th, 1895.

Digitized by Google

her, but she held to the belief that her friends avoided her on account of it. An examination showed that the nasal mucous membranes were normal excepting for a slight enlargement of the posterior extremity of the left inferior turbinate. On no occasion have I been able to detect any exposed bone, though I have searched for it with the smallest blunt probe, nor at any time has her breath been offensive. Besides this symptom, the patient has been the subject of various other climacteric troubles—e.g., heat flushes, occipital headache, giddiness, tinnitus, &c. The treatment has been mainly directed to her general condition by her medical attendant, and with the improvement of this her sensation of a bad smell has, *pari passu*, diminished; when the constitutional troubles are very slight the latter practically ceases. Only on one or two occasions, and as a placebo, have I prescribed an intra-nasal alkaline douche.

Remarks.—The first and third of these cases are interesting from an etiological point of view. The first is undoubtedly a post-influenzal neurosis, and similar cases have hitherto been described. The result of treatment would seem to point to the distribution of the olfactory nerves as the seat of the lesion rather than the olfactory bulb or a higher centre. The origin in the second case is obscure and the treatment less satisfactory than in either of the other cases. The last is undoubtedly a climacteric neurosis and reminds one of the various pharyngeal and laryngeal paræsthesiæ so commonly observed in females at this time of life. That such is the case is evident from the way in which the symptom has diminished and practically disappeared under treatment directed to the general condition of the patient, and the importance of recognising such cases is considerable when the possibilities of unnecessary local treatment are borne in mind.

Welbeck-street, W.

THE QUESTION OF LATENT HYPERMETROPIA IN THE VISUAL EXAMINATION OF CANDIDATES FOR THE PUBLIC SERVICES.[1]

BY W. M. BEAUMONT, M.R.C.S. ENG.,
SURGEON TO THE BATH EYE INFIRMARY.

IN Sir Thomas Longmore's "Optical Manual" it is laid down that "candidates for commissions in the Royal Navy are not considered eligible who are subjects of any degrees of myopia or hypermetropia";[2] and this is corroborated in the "Regulations as to the Defects of Vision which disqualify Candidates for Admission into the Civil or Military Government Services," edited by Mr. Macnamara, in which it is stated that a candidate's eyes must be emmetropic. There would appear, then, to be no question that theoretically lads who are hypermetropic are ineligible for the navy; and yet it does not do to accept this ruling too absolutely. A boy is brought to a surgeon and reads the far and near types at the regulation distance, his colour sense is good, and there is no strabismus, but nevertheless he has two or three dioptres of hypermetropia. He is not emmetropic—*ergo*, he is not eligible for the Royal Navy. The parents are informed of the decision arrived at, but they resolve to send him up for examination; he passes the vision tests with flying colours, and the surgeon who gave a pessimistic opinion is discredited. On asking the lad what manner of examination it was which he underwent it will be found that it merely consisted of a vision-testing process, and that no attempt was made to discover any latent hypermetropia. How, then, can the statement that the eyes must be emmetropic be reconciled with the fact that no investigation is made to find out the nature of the static refraction? The explanation is, I believe—and I have substantial grounds for the belief—that in all visual examinations for the public services it is customary to consider V= $\frac{6}{6}$ equivalent to emmetropia. The extraordinary error is made of looking upon Snellen's type as a test of emmetropia. Perfect distant vision and emmetropia are considered synonymous, whilst latent hypermetropia is a condition of refraction unrecognised in every examination for which these regulations have been devised. As a consequence, a candidate with six or eight dioptres of latent hypermetropia will pass, where another with two dioptres of hypermetropia, one of which is manifest, will be unerringly rejected. It may be asked, What evidence is there that latent hypermetropia is not taken into account?—and in reply I would submit that, although the regulations for the navy are most emphatic that a candidate shall be disqualified unless both eyes are emmetropic,[3] yet in another part of the same regulations it is stated[4] that "if the individual can distinctly see the letters of the line D = 6 at 20 ft. without glasses, and with each eye, he will pass, as far as his sight is concerned, the examination for the army, navy, or any other service, provided his colour sight is good and that he does not squint." Nothing can be clearer than this—it is a naval eleventh commandment that you may be guilty of as many dioptres of hypermetropia as you please, but do not let them be manifest. If further evidence were required to show that latent hypermetropia is disregarded in the visual tests of the navy it would be found in a consideration of the well-known fact that emmetropia is a decidedly unusual condition of refraction. In an examination of the refraction of infants Ely found that 69 per cent. were hypermetropic.[5] Hansen found 94·4 per cent. of hypermetropia in school children between the ages of ten and fifteen years. Dürr in Hanover found 59·6 per cent. of hypermetropia, 32·2 per cent. of myopia, and only 8 per cent. of emmetropia between the ages of ten and twenty years. But, as the eye does not attain its complete development until about the age of sixteen years,[6] some allowance may be made for hypermetropia in the examination of boys for the navy. In 4000 eyes reported on by Miles[7] 3045 were hypermetropic, 787 were myopic, and in 106 there was mixed astigmatism. A rigid adherence to an emmetropic standard for any public service must infallibly break down from lack of suitable candidates. Mr. Work Dodd[8] in some recent statistics gives 2 as the percentage of emmetropia in persons who made no complaint of their sight, but as these statistics are founded upon a small total number of cases it would probably be safer to take a somewhat higher proportion of emmetropia. But even if it be allowed that 20 per cent. of the would-be candidates are emmetropic it must be remembered that 80 per cent. of the boys who would otherwise become naval cadets are prevented by their hypermetropia; and if 80 per cent. are prevented by this cause how many of the remaining 20 per cent. are prevented by myopia and how many by other physical defects? At the present time no adverse opinion should be given of the chances of a candidate passing the vision tests of the Royal Navy on account of hypermetropia. It is well to remember that as long as the defect is latent it cannot be seen. Perfection in the abstract is an excellent ideal, but emmetropia as a *sine quâ non* for service in the navy is an impossible standard, and it should be acknowledged that certain degrees of hypermetropia are admissible. A vision standard of $\frac{6}{6}$, without reference to the refraction, is unfair to the candidates, because whilst it stamps them as fit for service on entering it leaves it doubtful whether a little later in life they will be compulsorily resigned on account of hypermetropia; and as this defect can always be readily discovered in childhood there is no reason why more definite rules should not be made. Certainly facultative hypermetropia should not be permitted to masquerade in the guise of emmetropia, and it should be clearly laid down what amount of error is admissible. The only question really is what that amount should be. For some of the public services regulations are already in existence. In the Indian Departments of Public Works, Forests, Survey, &c., the limit is four dioptres of hypermetropia, for the Indian Medical Service it is not more than five dioptres, and for the Indian Marine not more than one dioptre. In several of the Continental armies "neither officers nor recruits are rejected with hypermetropia equal to six dioptres, but they are allowed to wear glasses."[9] In the resolution adopted by the International

Medical Congress held in London in 1881 hypermetropia was considered sufficient to exclude a man from being a sailor if before the age of eighteen he had one dioptre of manifest hypermetropia.[10] In the British navy it is the rule, I believe, that officers are allowed to wear glasses after they have attained a certain rank, and there seems to be no satisfactory reason why this rule should not be considerably extended. If a hypermetropic officer can only read ⅞ with glasses it should be not only allowable but compulsory that he should correct his refraction, and then the exact number of dioptres of his hypermetropia is of little consequence.

Bath.

REMARKS ON THE HISTORY AND DISCIPLINE OF ENGLISH PRISONS IN SOME OF THEIR MEDICAL ASPECTS.

BY R. M. GOVER, M.D. ST. AND., F.R.C.P. LOND.,
MEDICAL INSPECTOR OF PRISONS.

IN the winter of 1773-74 John Howard made that celebrated journey which has been so graphically described by the late Dr. W. A. Guy,[1] and from which journey may be said to have originated the great prison reforms that have been in progress in England during the past 100 years. From the late autumn of 1773 to the spring of 1774, says Dr. Guy, there might have been seen, now at one country town, now at another, first of the midland districts of England, then of parts more remote, a gentleman on horseback, followed by his groom. It was not a time of the year when men take pleasure trips, and it was obvious that the gentleman had some serious business in hand, for he alighted at the county and borough gaols and spent some time there. Thence he would make his way to an inn, order the usual dinner for the good of the house, spread his note-book before the fire, and make a frugal meal of tea, bread, and (if he could get it) fruit. This gentleman was no other than John Howard, the lately appointed High Sheriff of the County of Bedford, the model landlord of Cardington, and he was travelling about in search of a precedent. He would find, if he could, one case at least in which the justices of the peace paid the gaoler of a prison a fixed salary. Had he succeeded he would have gone back to Bedford, near which town he lived, and would have strengthened the hands of the justices with a precedent, without which they had told him they could not act. But happily Howard failed. He could find no single instance in which a gaoler was paid a fixed salary. In lieu of salary the gaoler was allowed to charge certain fees, and these fees had to be paid by every prisoner, whatever the way in which he became such, and be paid before he could be permitted to leave the prison. He might be a poor debtor; he might be innocent of the crime with which he was charged and have been acquitted; or the grand jury might not have found a true bill against him; he might be a petty offender committed for some small theft, or a pressed man with home ties and duties, innocent of everything but not having a stomach to fight; or a man of violence—a highwayman, a burglar, a murderer; or a treacherous, fraudulent scoundrel, a forger, a receiver of stolen goods, a monster, a chronic fraud, or, perhaps, a raving madman. Whatever he was he must pay the gaoler's fees or remain in prison. The consequence was that innocent men by the thousand were kept locked up in prison—many for years or for life; many to die there, victims of gaol fever, confluent small-pox, and the other fatal maladies which spring out of the want of the prime necessaries of life—food, water, fuel, clothing, air, and exercise; some to be lashed into madness and some to lapse into fatuity. Howard could find no precedent for a better system of payment, but the winter's journey was not made in vain. He collected a mass of facts that at once led to great amendment of the law, and struck the death blow to the grossest and most nauseous tyranny that was ever suffered to reign in the midst of a free people. The winter's journey was not only no pleasure trip, but was one surrounded by incidents of danger and disgust as perilous as they were repulsive. When Howard went to his inn after the work of the day he used to spread his notebook before the fire. This he did that he might drive off the foul air it had absorbed in the prison. So foul was this air that many gaolers and even surgeons to gaols made excuses and would not go with Howard into the felons' wards. But nothing could appal him or turn him aside from the path of duty that he had chosen. This journey in search of a precedent, which revealed to Howard in all its revolting details the inner prison life of England, was the first step taken towards prison reform. Dr. Guy states that when, on the motion of Mr. Whitbread, Howard was summoned to lay his facts and figures before the Committee of the House of Commons, he left the House no alternative but immediate action. Two Acts were passed, the one abolishing the obnoxious payment of gaolers by fees, the other for preserving the health of the prisoners and preventing the "gaol distemper." In 1778 the Penitentiary Act was passed. This Act, which was permissive, provided for the placing of prisoners in cells alone, and it gradually came to be adopted in some of the county and borough prisons. But the cost of construction and the prejudice against separation created by the reports as to the results of the "solitary" system in America retarded the progress of a great reform. In 1784 rules were drawn up for the treatment and classification of prisoners, and in 1791 the Courts of Quarter Sessions became in some degree responsible for the periodical visitation and inspection of county and borough prisons.[2]

In the last decade of the last century the virulent gaol fever seems to have disappeared from prisons, though it is certain that a fever in no way distinguishable from gaol fever existed on board H.M.S. *Colossus* in 1796. This ship took on board, in the autumn of the year, a crew composed entirely of raw landsmen, the worst, according to Dr. Trotter, the fleet medical officer, that ever entered a man of war, of whom a great part had been discharged from gaols; and three or four times during the fitting of the ship fever broke out, one man falling ill, and then all the members of his mess. The disease made its appearance again during the cruise off the coast of Holland. Dr. Guy remarks that we owe to Dr. Trotter one of the most striking illustrations of the fact that a fever in all respects similar to the fever that formerly prevailed in prisons will break out on board ship when unwholesome conditions prevail, as starvation and cold, a scanty supply of impure water, deprivation and pollution of air, exclusion of light, idleness, filth, listlessness and grief. The French fleet which encountered ours on the glorious June 1st, 1794, was placed under the serious disadvantage of having such a fever on board all its vessels, while Dr. Trotter had "organised victory" by causing Lord Howe's fleet to go into action without a sick sailor on board. Slow but sure progress continued to be made in English prisons, and in 1818 there were few prisons without a chaplain. But even at this date no systematic employment had been found for the inmates of prisons; idleness prevailed in many county and borough gaols, and overcrowding was excessive. Nevertheless, the conditions were not such as to generate gaol fever. In 1835 and 1839 Acts were passed which further improved the administration of prisons, and inspection by Government officers was provided for; but it was not until 1865 that the provision of a separate cell for each male prisoner became compulsory. Even now legislation remained in great measure a dead letter owing to the fact that administration remained in the hands of independent local authorities, who failed to provide the requisite buildings, and were without experience save such as was gained by each in its own small area. The last great step in the direction of reform was taken in 1878, when the local prisons were transferred to the Government, and uniformity of administration for the first time became possible. There were then 113 local prisons in England and Wales; and such has been the effect of consolidation and concentration of authority that the number has been reduced to fifty-seven, with great and good results, the least of which is a large annual saving in the cost of management. Prisoners before trial are kept apart as far as possible from those undergoing sentence, they wear their own clothing (if it is not "utterly vile," as is often the case), they may provide their own diet, and may communicate freely with their friends. After sentence the prisoner becomes amenable to the progressive

Digitized by Google

stage system, and may raise himself by degrees to the fourth or highest stage, each promotion being attended with the acquisition of some privilege, as, for example, a larger supply of books and more frequent communication with friends and relatives. During all this time, and, in fact, during the whole period of his sentence in a local prison, the prisoner sleeps, takes his meals, and (usually) works in a separate cell. He is subjected to what is termed "separate confinement." This term is apt to convey to persons not familiar with the subject an erroneous impression of the conditions under which a prisoner is placed when undergoing confinement in a local prison. Although he is separated from other prisoners he is not left in solitude. He is visited frequently by various officers, he is well cared for, and his existence is rendered very endurable. Unless it be for idleness or misconduct he is not subjected to any depressing punishment. As I have previously remarked,[3] "instances are not wanting to show that separate or even solitary confinement for long periods is consistent with perfect mental and bodily health. The monks of the Grande Chartreuse live alone, each in his own 'cellule.' They remain silent for years, and hear nothing but the sound of their fellow monks' voices at the chapel services, yet visitors never fail to be struck with their healthy and contented appearance. Their food is simple but nutritious, and they are well provided with employment, so that their condition of life may be fairly compared with that of prisoners undergoing separate confinement at the present time in this country." It was not until the completion of Pentonville Prison that separate confinement was carried out continuously on a large scale and in a systematic manner, the results being recorded in detail in reports accessible to the public. Pentonville Prison was opened in December, 1842, and the Commissioners appointed for the government of the prison made favourable reports as to the condition of the prisoners from year to year until 1853, when the then new established convict system was in full operation, and the prison came under the control of the Directors of Convict Prisons. The deterrent and reformatory effects of imprisonment were attained without injury either to the bodily or mental health of the prisoners. There was but little sickness among them, cases of insanity originating in the prison occurred but seldom, and deaths were few. It appears evident from the minute detail into which the Commissioners enter in their reports, and from many of the expressions employed, that they were apprehensive of evil or misfortune of some kind, but these apprehensions were not justified by the result. In consequence of the success of the system of discipline carried out at Pentonville Prison a large prison after the same model was erected at Wakefield, and separate confinement was carried out there, with even fewer mental cases than occurred to Pentonville Prison. The same system in all its main features has been carried out, and continues to be carried out up at this day, in that and other local prisons without the occurrence of any cases of mental or bodily affection that can be reasonably ascribed to the influence of separate confinement.

In the consideration of the question as to what amount of separate confinement may be borne with safety the experience of the present Board of Commissioners during the last seventeen years appears to me to be of much greater importance than any recorded experience of former times. "The conditions forty or fifty years back" (I quote the memorandum to which I have already referred) "were not those of to-day. Sanitary science has advanced, construction has improved, the causes of disease are better understood, discipline and diet have been modified and changed, and experience has ripened. That experience shows that separate confinement under present conditions is not injurious to the mental or bodily health, and may be continued indefinitely." Separate confinement (using the term in its technical prison sense) lends itself well to any modifications that may be deemed necessary, in the case either of individuals or bodies of prisoners, and is compatible with the carrying out of industrial labour in workshops or with outdoor labour of any kind available. At whatever work the prisoner might be employed he would still sleep and take his meals in his own cell, which he would, in fact, occupy in the evening and at all times when not at work or at exercise or at the chapel services. The medical aspects of prison discipline as now conducted in this country have some of them been presented in my annual notes appended to the Reports of the Commissioners and Directors, and are all of them full of interest. It is not my object to enter into elaborate particulars in this short paper, which deals only with generalities, but there are one or two points to which I may call attention without entering into any tedious statistical or technical detail. Fever of any kind is now of rare occurrence in the prisons of this country, and when it does occur is usually imported, while diseases indicative of defective sanitary arrangements, as erysipelas, are conspicuous by their absence, notwithstanding that many of the inmates of prisons are drawn from quarters where infectious diseases are rife. The average daily population of the local prisons of England and Wales for the six years commencing April 1st, 1888. was 14,119. The mean annual death-rate for this period was 7·6, and the mean annual rate (per 1000 of the population) of releases on medical grounds was 4·5. Reckoning, however, the releases on medical grounds as deaths, and adding them to the actual deaths, the mortality was 12·0 per 1000 per annum for the period of six years. To count all the releases on medical grounds as deaths is, however, unfair to the prisons, seeing that prisoners are frequently released for diseases that may not be fatal, as chronic abscess, debility, abdominal tumour, cataract, paralysis, bronchitis, and so forth. A deduction of at least 25 per cent. for these cases should be made before the influence of releases on medical grounds on the death-rate can be accurately estimated. Making that deduction, the death-rate per 1000 per annum for the six years ending March 31st, 1894, may be fairly represented by the figure 10·9.[4] It may be doubted whether by any future efforts the ratio can be reduced materially below that point.

The number of cases of insanity proportionally to the population of the local prisons of England and Wales will appear very high or very low, according to circumstances and the way in which the matter is presented. If all persons remanded to prison for medical observation, and reported to the police authorities to be insane, are credited to the prisons, the number will appear to be very large; and if to these are added those who are found to be insane within a very short period of reception, as well as those found insane on arraignment or on trial, the number can be made to rise to the extravagant figure of 200 or more per 10,000. But if only those insane prisoners are taken into account who have been sufficiently long in confinement to render it possible that the insanity may have originated and developed in prison, the number will be very small. Everything depends upon the statistical method employed. It does not, of course, follow that a prisoner is sane when he is admitted into prison because no symptoms of insanity happen to be manifest at that particular moment. The Rev. W. D. Morrison, in his evidence before the late Departmental Committee,[5] mentions the case of a man who was six months or more in Wakefield Prison before it was discovered that he was insane. The Rev. Mr. Morrison says: "I was convinced that he was insane, but the doctor could not find any trace of it, and I could not find any definite trace of it for some time, but one day he was talking to me, and he said, 'I am the man that tried to shoot the Duke of Edinburgh at Melbourne.' That was his delusion, that he was the man that tried to shoot the Duke of Edinburgh at Melbourne, and that is how it came to be found out." And yet, according to the method of the Rev. Mr. Morrison himself, this case would have gone to swell the number of cases in which insanity arose in prison, and were (in his opinion) probably caused by prison treatment. The evidence of Mr. Stone, the chairman of the Visiting Committee of Birmingham Prison, before the late Departmental Committee, is probably as conclusive as a formidable array of statistics, and is decidedly more racy and interesting. I may premise that the prison at Birmingham may be taken as a representative prison, and that there is no reason to suppose that it differs in the smallest particular from other local prisons in respect of discipline and management.

"Q. 2681.—The Chairman (Mr. Herbert Gladstone): You say that you think that insanity in the Birmingham Prison is very rare?—Very rare indeed. Our returns of insanity are about 0·02. We have a mere nothing of it.

"2682.—And those cases that you have come in you do not think have been affected by prison?—Sometimes it is the

result of delirium tremens; that is really in the system before they come in.

"2683.—You have no reason to think that the prison discipline acts upon them?—No; I have very carefully watched them, and I have had a large mass of figures got out to produce to you if you want them, but it is not 1 per cent., it is not a quarter of 1 per cent., and we have 8000 prisoners who went through the gaol last year."

Before concluding this brief paper it may perhaps be interesting and instructive to glance back along the century now about to expire and to compare the English prisons of 100 years ago with those of the present day. In 1795 convicts were herded together in hulks, in which no attempt was made to check the evils of association, and "vice, profanity, and demoralisation" ran riot. Great evils—among them the indiscriminate crowding together of prisoners—were still prevalent in the county and borough prisons, but the reports of John Howard had begun to alarm the national conscience, and justices were beginning to visit and inspect these prisons at periodical intervals. There were nearly 600 prisons in the United Kingdom. In many of them no attempts were made to divide the males from the females, gaol fever was still prevalent, and horrible scenes of wickedness were occasionally enacted. John Howard had made his final journey through Holland, Germany, Prussia, and Livonia to Russia and Lesser Tartary, and had been laid to rest at Cherson, in Russia, where his remains have lain undisturbed to the present day; he had travelled 60,000 miles, and it is believed that he spent from first to last £30,000 of his own money in the prosecution of his self-imposed duties. If he could now revisit this country he would find that each inmate of the local prisons has a cell of a capacity of about 800 cubic feet to himself, and that this cell, which is in the cleanest condition possible, is furnished with special arrangements for the withdrawal of used-up air and the supply of fresh air. He would observe that the furnishing of the cell, though not luxurious, is sufficient for the needs of the prisoner; and he would also observe that the prisoner is supplied with the necessary utensils, with good food, with abundance of water, with books, and with a bell-pull by means of which he can draw the attention of the officer of the ward. He would find that the food is sufficient and well prepared, that a well-arranged hospital is provided for the care and treatment of the sick, and that on the expiration of his sentence Discharged Prisoners' Aid Societies are ready to take him in hand and to assist him in making a fresh start in life. Although the prison system of the present day in this country, like other human institutions, may not be perfect, it may be questioned whether the next hundred years will witness evolutionary changes comparable to those that have taken place in British and Irish prisons since 1795. The next great step would seem to be the recognition by society of its duties in the direction of the prevention of crime, and the discharge of its duties in such a manner as to convert the possible criminal into a useful member of the commonwealth. Whether the somewhat pessimistic doctrines of the criminal anthropologist be accepted as the basis of action, or the more hopeful view of those who regard a proclivity to the commission of crime as the natural outcome, in the majority of cases, of unfavourable surroundings from infancy upwards, there can be no doubt that the criminal elements in society may be largely reduced by such social reforms as the prevention of overcrowding, by attention to the details of sanitation, by judicious education, and by such training as will tend to eradicate habits of idleness. A distinctive feature in the character of the habitual criminal is a distaste for regular labour. The changes that are destined to take place in prison administration, and the measure in which society will interfere to prevent the genesis of the criminal during the next century, cannot, perhaps, be even roughly indicated, but it cannot be doubted that the good work initiated by John Howard will be continued in such manner and with such effect that some, at least, of the criminal classes will lose their characteristics as criminals, and will be finally absorbed into other classes of the social organisation.

MR. GEORGE MÜLLER, of Ashley Down Orphan Houses, Bristol, reached his ninetieth birthday a few days ago, and has received numerous presents and congratulations from friends in all parts of the country.

CASE OF HÆMATOCELE SUPERVENING ON AN ABORTION.

BY J. O'REILLY, M.B. DUBL., M.CH.,
SURGEON-LIEUTENANT-COLONEL, ARMY MEDICAL STAFF.

THE subject of this case was a woman about twenty-eight years of age, strong and healthy. She had been married four months and was about three months advanced in pregnancy. She had just returned from a long journey from a distant part of Germany, and had experienced a very rough passage across the channel. On Oct. 8th, 1894, the day after her return to Guildford, severe intermittent pains in the lower part of the abdomen set in. On being called to see her I found the uterus firmly contracted and all the symptoms pointing to an impending abortion. During the next two days there were frequent uterine pains. Perfect rest in bed was enjoined and opiates administered. About 8 A.M. on the morning of the 11th I received an urgent summons to see her, and I asked my friend Mr. Sells of Guildford to accompany me. On our arrival we found that an abortion had taken place and that an immense quantity of blood had been lost. A large chamber utensil was full of clots. The umbilical cord—untied—had slipped up into the vagina. I gave chloroform, and Mr. Sells removed a large number of blood-clots from the vagina, and eventually, but with great difficulty, managed to extract the placenta. The patient was quite blanched from loss of blood, complained of severe abdominal pain, and was in a state of almost total collapse. Ergot and opium were administered freely. Soon after the removal of the placenta the uterus contracted firmly, and no more blood was lost per vaginam. About an hour afterwards, however, the symptoms of shock became more pronounced, and on an examination of the abdomen being made a large mass was found occupying the site of the uterus. It was at first thought that the latter might be distended with clots, and it was accordingly washed out with warm boric solution. Nothing, however, came away. This was puzzling. A closer examination of the lower part of the abdomen revealed a large smooth elastic swelling in the hypogastric region, and on introducing the finger into the vagina a tumour could be distinctly felt pressing on this canal. Mr. Sells and I then came to the conclusion that this could be nothing else than a hæmatocele, due probably to an effusion of blood from some ruptured vessel into the sub-peritoneal tissue around the uterus. A smaller swelling was discovered to the left of the central one—apparently a smaller hæmatocele due to an effusion of blood in the course of the broad ligament. Nothing could be done except to keep the patient perfectly quiet in bed, support her strength, and administer opiates to relieve the pain and restlessness. She remained in an alarmingly weak state for some days, and suffered from profuse perspirations—generally in the early morning—and from frequent attacks of distressing vomiting. The temperature varied from 100° to 102° F., and the pulse was very weak and rapid. The smaller swelling cleared up in about a month. Shortly before this disappeared another appeared in the right iliac region and was attended with a good deal of abdominal tenderness and pain and distressing tympanites. The temperature rose to nearly 104°. This was probably an attack of pelvic cellulitis with subacute peritonitis, and it subsided in about a week under the free administration of opium and hot fomentations. The further history of the case—a dreadfully harassing and trying one to the patient and to her attendants—may be briefly summarised. The prominent symptoms were frequent profuse sweats, distressing irritability of the stomach, obstinate constipation, occasional attacks of severe abdominal pain, and constant tympanites. The temperature generally varied between 100° and 103°, though sometimes touching 104°, and the pulse was always very rapid—115 to 130—and occasionally of a running character difficult to count. The irritability of the stomach was so great that it was with extreme difficulty she kept down any nourishment. She became reduced to an alarming state of exhaustion and emaciation, and it was only after trying many kinds of food and stimulant that we succeeded in finding some that could be retained. These were the only things she could retain, and they enabled her to bear up successfully against her wasting illness. About the beginning of December the tumour, which had never

Digitized by Google

shown the slightest sign of any diminution in size, showed signs of enlargement, and indications were soon apparent that matter was forming and was making its way towards the surface. Soon a good deal of inflammatory thickening and hardness was observable all round the tumour, and it became completely and securely encysted. The pain in it now became agonising. Frequent and strong hypodermic injections of morphia were required. I may here remark that all through this trying case opium was our sheet-anchor. The quantity of it that the patient took by the mouth, by means of suppositories, and by hypodermic injections of morphia was enormous. For three months she was more or less continually under its influence. On Dec. 17th the abscess pointed externally at a spot two inches and a half below and slightly to the left of the umbilicus. The abscess wall could be made out to be adherent to the skin of the abdomen over an area equal to that of a florin. Chloroform having been administered a small incision with a scalpel was made through the skin in the centre of this area. This incision was carefully enlarged with a bistoury on a director, and the lips of the incision were then separated by the blades of a dressing forceps. About a pint of the most terribly fetid dark pus mixed with broken-down blood-clots was evacuated. A drainage-tube was inserted, the wound was dressed twice daily, and for several days the discharge was most copious and offensive, saturating the dressings and causing, by its intolerable odour, great distress to the patient. When the quantity had lessened somewhat the abscess cavity was syringed out twice daily with strong boric solution. This acted excellently. A few hours after the abscess was opened the temperature sank to normal and never afterwards rose above it. Convalescence was uninterrupted. In about six weeks the wound had completely closed. The patient is now in excellent health. The menses—which had been completely suppressed during her long illness—reappeared about the beginning of March.

Guildford.

MODIFICATION OF THE DISTAL LIGATURE FOR ANEURYSMAL DILATATION; A SUGGESTION.

BY PATRICK J. HAYES, M.D. R.U.I., F.R.C.S. EDIN.,
SURGEON TO THE MATER MISERICORDIÆ HOSPITAL, DUBLIN.

THE majority of hospital surgeons from time to time encounter cases of aneurysm where, the possibility of dealing with the proximal portion of the diseased artery being out of the question, the problem of inducing coagulation within the sac, either by the Brasdor-Wardrop application of ligatures on its distal side or the extremely hazardous introduction through the sac wall of foreign agents, must be considered. I have occasionally observed notable delay with regard to evidence of improvement after distal ligature, and in the case of a thin-walled aneurysm such retardation may entail rupture of the tense, frail wall where otherwise cure would have been the result of operation. It occurs to my mind that thrombosis can be caused to extend from a distal point rapidly and safely to even a deeply situated aneurysm by such a measure as the following.

The surgeon selects a favourable site for ligaturing the vessel or vessels on the distal side of the aneurysm, and in the event of there being two trunks for ligation he determines which is to be doubly ligatured and divided. Rough measurement of the distance between the aneurysm and the point for double ligature, with division of the artery, is now to be made and a piece of sterilised catgut is to be cut, its length being sufficiently in excess of the measured interval. The arterial trunk having been exposed, a double aseptic silk ligature is passed beneath it and the loop divided so as to leave cords with a space of, say, half an inch between them. The more distal ligature is now to be knotted and its ends removed, but the proximal ligature is to be only loosely tied with a single knot, which will serve merely to moderately compress the arterial walls. It will afford additional help and security if the artery needle be maintained in position beneath the vessel up to the time for tightening the proximal ligature. The next and distinctive step is this:—A small opening is to be made into the lumen of the artery, midway between the ligatures, and through the aperture a slender cannula, occupied by nearly half the length of aseptic catgut already referred to, is to be introduced and directed towards the proximal or aneurysmal portion of the vessel, until it will have passed just within the part lightly compressed by the proximal ligature. The catgut is now to be gently pushed on through the cannula until the surgeon estimates that its free end will have reached, or perhaps entered, the aneurysmal dilatation. The cannula is then to be withdrawn and the proximal ligature to be firmly tied on the artery corresponding to the distal end of the intra-arterial cord of catgut. Subsequently the artery and free part of the catgut are to be cut across at the site of aperture midway between the ligatures. The object attainable by introducing into the lumen of the vessel a bougie of catgut long enough to reach the sac can be readily understood. The foreign substance must soon become enveloped in a coating of fibrin, and, as it were, act as a gubernaculum for extension of the coagulating process within the aneurysm. At the same time, the sac wall will not have been injured or weakened by any needle puncture, whilst risk of distant embolism will have been guarded against by the previous ligation of the trunk or trunks on the distal side. The question of danger from hæmorrhage during puncture of the artery can easily be answered. The finger and artery needle, supplying points of pressure and counter-pressure, will afford absolute security whilst the opening is being made and the introduction of the cannula being effected. The cannula is well filled by the catgut, so that when the proximal ligature is tightened on its tip little, if any, blood can escape through the instrument. Once a sufficient length of catgut has been introduced the tip of the cannula is withdrawn and the encircling ligature made perfectly tight on the artery containing the clot-determining catgut.

It seems rational to infer that aneurysms, otherwise beyond the reach of surgical treatment, may, with at least comparative safety, have conducted to them thrombi capable of inducing cure by coagulation. Moreover, the catgut, being adapted for solution and absorption under the agency of leucocytes, will, after having effected its purpose, gradually disappear, and with it, in all probability, redundant blood-clot occupying the arterial lumen.

Dublin.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

ERYTHEMATOUS RASH AFTER OPERATION DUE TO THE ENEMA, NOT TO THE ANÆSTHETIC.

BY H. BELLAMY GARDNER,
ASSISTANT ANÆSTHETIST TO CHARING-CROSS HOSPITAL.

AMONG surgeons of the day there is a very generally prevailing impression that the appearance upon a patient of a red rash after any surgical procedure may be due to the anæsthetic which has been employed. I should like to bring forward a few observations which will tend to relieve the anæsthetic from this accusation. I have now full notes of nine cases of this erythema, occurring chiefly among gynæcological patients, in two London hospitals. The rash is red, raised, almost papular in appearance, arising first about thirty hours after operation on the skin of the thighs and buttocks, then upon the chest, wrists, cheeks, elbows, forearms, and back, preceded and accompanied by a feeling of heat and irritation of the affected part, without pyrexia, lasting two and a half to three days, and fading off subsequently without desquamation. Six of these patients had enemata of hard yellow soap and warm water five hours before operation, when gas and ether were administered to produce anæsthesia. One patient, a child, was prepared in the same way and had chloroform as an anæsthetic. Two patients had exactly similar enemata with an exactly similar erythematous rash without the administration of an anæsthetic at all. In one of the first six cases the rash became intensified by a second enema given the next day. In another the woman stated she had had an exactly similar rash after an enema four months previously without any use of anæsthetics. The child had a slight recurrent rash after a second enema when the first rash had disappeared. Experience of anæsthetics shows that a transitory flush upon the

Digitized by Google

throat, neck, and chest during the early stages of administration, which disappears entirely in a few minutes, is all that can be regarded as directly due to this source. Four communications[1] have appeared in the London medical journals citing twelve cases in all of erythema after an enema; six of these had no anæsthetic and one was just about to have chloroform when the rash was discovered. Various explanations of the rash have been offered, but as my cases all had the particular kind of soap mentioned, and no rash resulted after the use of soft soap enemata in 400 other cases, I cannot seriously doubt that the kind of soap used is the main factor in producing the rash. On analysis the hard soap only contained a trace of iron, and was very slightly alkaline in reaction.

CASE OF EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

BY E. C. LONG, L.R.C.P. LOND., M.R.C.S. ENG.,
PRINCIPAL MEDICAL OFFICER, BASUTOLAND.

THE patient was a well-developed Basuto aged twenty-two years, employed by the Government as a post-rider. There was no history of syphilis in his family, and he had four brothers and two sisters all living and healthy. He had never been ill as far as he could remember. On June 10th he returned from his usual post journey, and that evening complained of headache and noticed that his body was covered by an eruption. Chicken-pox was epidemic in the camp at this period. The following morning on waking he found he was quite blind in the right eye, and presented himself for treatment at the Government Hospital. The eye appeared normal, but ophthalmoscopic examination showed embolism of the right central artery. Retinoscopy showed both eyes to be hypermetropic to the extent of 2·75 D. Three days afterwards the white haze which at the first had obscured the vessels round the centre of the disc had moved outwards, leaving the vessels in the centre well defined. The veins appeared much larger towards the periphery and the cherry spot smaller, and the white haze round it had also extended in an outward direction, while the whole fundus appeared paler. Some of the scabs of the varicellar eruption were falling off and a few fresh vesicles were seen. After this the haze gradually cleared and on July 4th the following note was made: "Edges of disc well defined. It is much whiter and along the course of the arteries is a bright white line. The fovea presents a mottled appearance of red on a white ground, the white being highly refracting and having an almost metallic appearance. The patient continues quite blind in the affected eye."

The case seems interesting from the fact of its occurring in a young subject suffering from such a simple malady as chicken-pox. Careful examination failed to detect any evidence of either cardiac or renal trouble. The only point in connexion with a possible cause of which I can think is that the evening before the embolism occurred the patient rode some thirty miles with his post, the temperature being some six degrees below freezing.

REMOVAL OF A LARGE INSECT FROM THE HUMAN EAR.

BY EDWARD ARMITAGE, M.R.C.S. ENG., L.R.C.P. LOND., D.P.H. CAMB.,
GOVERNMENT PHYSICIAN FOR THE WAILUKU DISTRICT; PHYSICIAN TO THE MALULANI HOSPITAL, ISLAND OF MAIN, HAWAIIAN ISLANDS.

CASES of insects having found their way into the human ear are frequently cited, but, so far as I am aware, few authenticated cases are to be met with in the medical journals. The following case seems to me to be worthy of notice on account of the large size of the insect in comparison with the dimensions of the passage in which it was embedded.

On the morning of July 1st, 1895, I was summoned to my office to see a Portuguese aged thirty-four, who complained that an insect was lodged in his ear and requested me to remove it. The patient was a man of unemotional appearance and phlegmatic temperament, but he seemed to be suffering considerably. On drawing the auricle backwards and looking into the meatus, without the aid of a speculum I could not perceive anything; but after syringing with warm water for a few minutes I noticed the wing-sheaths of an insect appear. Using a pair of forceps I extracted a cockchafer. The insect was nine-twelfths of an inch long and five-twelfths of an inch broad at the junction of the head with the thorax. The long antennæ measured eight-twelfths of an inch. The creature was firmly fixed in the osseous meatus and required some force to remove it. Attached to it were particles of cerumen. The patient stated that he was awakened at 1 A.M. by a disagreeable sensation in his ear, and that in endeavouring to remove the cause he had pulled off portions of the wing-sheaths. The total length of the insect from the point of the head to the termination of the wing-sheaths was probably one inch. Subsequent examination with the aural speculum showed one of the legs fixed to the tympanic membrane, but he would not undergo further treatment for its removal, expressing himself as perfectly satisfied with what had been already done. Afterwards he experienced a "rushing noise" in the ear for about three hours, and then his aural sensations became normal.

ST. BARTHOLOMEW'S HOSPITAL.

TWO CASES OF FIBRO-ANGEIOMA OF THE NASO-PHARYNX TREATED BY OPERATION; REMARKS.

(Under the care of Mr. ANTHONY BOWLBY.)

CASE 1. *Fibro-angeioma of naso-pharynx; excision of upper jaw and removal of growth after ligature of the external carotid artery.*—A man aged twenty-one years attended the department for diseases of the throat at St. Bartholomew's Hospital on March 9th, 1894, on account of severe epistaxis. The history he gave was that five years previously he first had severe bleeding from the nose, and that since that time he had never been able to breathe through the nostrils; even before this time, however, he had suffered from occasional epistaxis and continued to do so subsequently. Four months before admission he consulted a medical man in Dantzig, who told him he had polypi and removed something from his left nostril, an operation which was followed by epistaxis for three weeks. Soon after this the patient came to England and was admitted as an in-patient at the Central London Throat Hospital, where more growth was removed from the nose, with considerable loss of blood. Since this time hæmorrhage from the left nostril had been almost continuous. An examination of the patient showed that he had evidently lost much blood, for, although a thickly built, swarthy man, his lips were pale, his pupils dilated, and his pulse rapid and feeble. He was bleeding from the left nostril only, and on mopping away the blood there could be seen a growth which occupied the whole of the nasal cavity on this side. After plugging the nostril an examination of the throat showed that very little blood was running down the pharynx, but that the soft palate was bulged and moved very little on phonation or deglutition. With the finger a large growth could be felt blocking the whole of the naso-pharynx and attached to the posterior pharyngeal wall. The nose itself was not much deformed, but was distinctly broadened at its base. The patient was put to bed, kept quite quiet for several days, and fed well; the bleeding from the nose was stopped after twelve hours by careful plugging, and the general condition improved quickly. Further examination now showed that

Digitized by Google

the growth in the left nostril was not nearly so red and semi-translucent as a mucous polypus and that the right nostril had no growth in its lower and anterior parts, but was quite blocked posteriorly. It was considered that the growth was a fibro-sarcoma of the naso-pharynx, and at a consultation on March 15th it was decided to remove a small portion of the tumour for microscopical examination, and not to attempt its extirpation except by completely exposing its attachments. The removal of a portion through the left nostril was followed by most profuse hæmorrhage, which was with difficulty arrested by plugging, and continued slightly for four days. A microscopical examination of the tissue thus obtained showed that the stroma was entirely fibrous, without any appearance of sarcoma, and that the greater part of the section was composed of innumerable small bloodvessels and cavernous spaces with practically no muscular tissue in their walls. After a further delay of a week for rest in bed and more feeding an operation was performed, with the kind assistance of Mr. Lockwood, on March 30th. The left external carotid was first ligatured in the neck by the usual incision, and this wound was at once closed. The upper lip was then split in the middle line and an incision was carried along the left side of the nose to the inner angle of the orbit, and when the soft parts had been reflected the nasal process of the superior maxilla was divided and the nostril explored. As the growth was found to have no intra-nasal attachment the left superior maxilla was next excised and the tumour exposed. Bleeding was arrested by sponge pressure, and then an attempt was made to avulse the growth with strong forceps. It was, however, so firmly fixed that no efforts could dislodge it. It was finally separated from the pharynx with a raspatory and torn away from the base of the skull, bringing away with it a small piece of bone from this region. The removal of the tumour was followed by a gush of blood, which was quickly stopped by sponge pressure and did not recur; in a few minutes the wound was quite dry. The skin flap was readjusted and the pharynx and nostrils plugged with iodoform gauze. After the operation the patient was much collapsed, but with the use of brandy, beef-tea enemata, and injections of strychnia he rallied in a few hours and made an uninterrupted recovery, both the facial incision and that for the ligature of the carotid healing by first intention. Six months later he continued well, and, having been fitted with a false palate and teeth, showed but little deformity. The nostrils remained clear, and there was no growth in the pharynx. He was again examined fourteen months after the operation, when the pharynx was found to be quite healthy.

CASE 2. *Pulsating fibro-angeioma of naso-pharynx; removal of tumour after resection of the hard palate and division of the soft palate.*—The patient was a healthy young man aged nineteen years who was sent by Mr. Trotter of Brandon on June 19th, 1894. His history was that for eighteen months past he had been quite unable to breathe through either nostril, and felt as if there was a swelling in the back of his throat. For a year he had noticed some watery discharge from the nostrils, but had never suffered from epistaxis. Nine weeks before he came under notice he became an in-patient at Addenbrooke Hospital, and on three or four occasions was treated by the application of the galvano-cautery and electrolysis. On admission he presented the usual appearances of nasal obstruction, the mouth being habitually open and the nostrils collapsed; the nose was not materially altered in shape. By anterior rhinoscopy it could be seen that the posterior nares were occluded by a red mass, which felt very firm when touched with a probe, and bulged into the nostrils. When the mouth was widely opened the palate was seen to be pushed down and almost motionless, and when the head was thrown back the rounded outline of a tumour was exposed. The hard palate was also depressed so that its arch was almost flattened out posteriorly. Examination with the finger showed that the soft palate was firm and resistant and that the hard palate was elastic and capable of being slightly bulged by firm pressure. On passing the finger behind the soft palate a firm rounded tumour could be felt occupying the entire pharynx and fixed both to the palate and to the posterior wall of the pharynx; it did not bleed on being touched. Mr. Thomas Smith saw the patient with Mr. Bowlby and agreed that it was a growth which [illegible] for its safe removal, and [illegible] might be done it [illegible] by dividing [illegible] much bone as it might be necessary to remove. The operation was performed on July 3rd, with the assistance of the house surgeons, Mr. Rudolph Smith and Mr. E. Cross. Tracheotomy was done, the cricoid ring was plugged with sponge, and a Durham's tube was inserted. The soft palate was next split in the middle, and the growth, which was found to be adherent to it, was very cautiously detached; the soft palate was then cut away from its bony attachments, and the muco-periosteum of the hard palate was turned back so as to expose the palatine arch as far forward as the teeth. The detached soft palate and the muco-periosteum were then held aside by five long silk sutures passed on each side of the incision. When this had been done it was found that the hard palate had been almost quite thinned away by the pressure of the growth on its posterior part, and the thinned bone in this region was next easily removed with bone scissors, so as to make a gap about three-quarters of an inch wide. The central part of the hard palate anterior to this was then removed with a chisel and mallet as far forward as a point immediately behind the incisor teeth, a triangular portion of bone with the apex forward being then taken away. When this had been done an excellent view of the tumour was obtained. It was red, covered with mucous membrane, and pulsated very obviously. When compressed with a sponge it collapsed to about one half of its size, and when pressure was removed it enlarged to its former bulk with a series of pulsations like an aneurysm. It was evident that it contained large cavities full of blood, and after some deliberation as to the best mode of removing it Mr. Bowlby avulsed it with a large, curved, steel elevator passed behind the mass; its removal required considerable force, but the toughness of the growth prevented its tearing, and the whole tumour came away in one piece. The anticipated rush of blood, which was considerable, was arrested by plugging the pharynx with sponges, and on the removal of the latter after a few minutes the bleeding was seen to have almost stopped. It was then found that the tumour had been attached to the base of the skull and the posterior wall of the pharynx. The whole of the incision in the soft palate was now sutured, and the muco-periosteum was also sutured across the clefts in the bone. The naso-pharynx was plugged with iodoform gauze, and the tracheotomy tube was left in. Two days later, as there had been no bleeding, the tube was removed and the plugs were changed. The patient suffered comparatively little from shock and made an uninterrupted recovery. The palate healed completely, and the stitches were removed three weeks after the operation. Three months later the patient came to show himself, when it was found that bone had been reproduced along the entire cleft and that the soft palate moved freely on respiration and phonation. The voice also was clear and strong, and nasal respiration was free. A year after the operation Mr. Bowlby saw him again and found no sign of new growth, and in September, 1895, Mr. Trotter wrote in reply to inquiries that the patient remained quite well. An examination of the tumour showed that its cut section was white and fibrous. It contained one large blood cyst, as big as the end of the index-finger, and lined by a smooth membrane, as well as several smaller ones. Its size after removal was not as much as half its size when in the pharynx. Microscopically examined, the tumour was seen to be composed of dense fibrous tissue, embedded in which were innumerable vessels and many irregular cavernous spaces, which only differed from those of erectile tissue in not containing any muscular tissue in their walls.

Remarks by Mr. BOWLBY.—There are two points of interest in these cases which are of some importance surgically and which are worthy of a brief consideration: first, the nature of the tumours; and, secondly, the operations undertaken for their removal. With regard to the first point, it is my opinion that most of the sessile tumours of the naso-pharynx which occur in young male adults are angeiomatous rather than sarcomatous. It is true that they are very commonly spoken of as fibro-sarcomata, but from what I have myself seen of that growth I am sure that structurally they do not merit the term. The tumours in question are composed of very dense fibrous tissue containing practically no cell elements and not resembling sarcoma either to the naked eye or under the microscope. It is true that they are somewhat prone to local recurrence, but I think that this is often due to the fact that, owing to their wide attachment and the situation in which [illegible] portions are liable to be left at the time of [illegible] angeiomatous element is, I think, an [illegible] factor in the

growths, though it is seldom so largely developed as in Case 2; and it is rare to find tumours in any situation in which pulsation is so marked as it was in this case. The reason that the angeiomatous nature of these growths is often overlooked is that after removal there are not only no obvious vessels to be seen on a freshly cut surface, but that on microscopical examination also the vascular spaces appear as mere slits in the section, there being as a rule no definite vessel wall forming the channel for the blood.

Secondly, with regard to the operation by which these tumours may be removed, it must be conceded that no single operation is satisfactory for all cases. There is, however, one thing essential whatever method is adopted—namely, that the growth be completely exposed before any attempt is made to remove it. It is further important, in view of the nature of the tumour, that when so exposed it should be torn away from its attachments as rapidly as possible, and that it should not be cut into or removed piecemeal. These precautions are necessary on account of the great vascularity of the growths in question, for hæmorrhage is much greater than in cases of sarcomatous or epitheliomatous tumours, and the danger of a sudden and profuse hæmorrhage is a very real one if these precautions be neglected. In Case 1 the risk of operation was increased by the loss of blood previously, and it was on this account that the external carotid was ligatured, with the result that much less blood was lost in the facial incisions and in clearing the bone than is commonly the case. It was also with a view of getting the operation completed as quickly as possible that the whole maxillary bone was removed at once. But in the second case the patient was young and vigorous and quite able to stand the more prolonged operation which was decided on. The operation performed in Case 2 may be described as a modification of that of Nélaton, from which it differs, however, in the section of the bone, the treatment of the soft palate at the time of operation, and in the restoration of the palate by suture. This restoration of the palate was recommended by Sédillot, but the operation itself does not appear to have been actually performed by this surgeon. In the case of my own the complete retraction of the soft palate and of the muco-periosteum of the hard palate enabled as much bone to be removed as was required to expose the whole of the pharyngeal vault and the tumour which occupied it, so that when this had been done there was as much room as could be desired for the actual removal of the growth. I am, however, convinced from cases I have seen that the splitting of the soft palate does not give sufficient room; whilst, on the other hand, I feel sure that when the growth is limited to the naso-pharynx the operation practised in Case 2 gives quite as much room as can be desired and is not open to the objection of causing subsequent deformity such as results from osteoplastic section or excision of the upper jaw. I was much indebted to Mr. Smith in Case 2 for his advice both before and during the operation.

BRADFORD INFIRMARY.

PERFORATING GASTRIC ULCER; RESECTION OF THE STOMACH; DEATH AFTER ELEVEN DAYS.

(Under the care of Mr. W. H. HORROCKS.)

A MARRIED woman aged thirty-three years was admitted to the Bradford Infirmary on Dec. 30th, 1894, with symptoms pointing to perforation of the stomach consequent on gastric ulcer. For several years she had been under medical treatment at intervals for gastric troubles, vomiting, and pain after food. Blood had never been seen in the vomit. For the past few months the symptoms had been less severe. Early on the day of admission she drank some hot tea. This was immediately followed by acute epigastric pain, faintness, and profuse sweating. As the pain continued to be very severe she was seen about four hours afterwards by her medical attendant, Mr. Mercer. Considering the previous history and the onset of the acute symptoms, Mr. Mercer strongly suspected perforation and asked Mr. Horrocks to see the patient with a view to laparotomy being performed. When seen ten hours after the first symptoms she was lying in bed with the knees slightly raised. Her expression did not indicate severe pain unless an effort was made to turn, when acute pain was shown by the facial aspect. The pulse was 98, good, regular, but somewhat quicker than it had been at the previous visit. There was a marked cardiac, basic bruit, apparently hæmic in nature. She complained of persistent burning pain referred to the tip of the tenth left rib. The abdomen was not distended, but the muscular walls were tense, so that deep palpation met with resistance. There was no localised tenderness in the epigastrium. An impaired percussion note was elicited in the epigastric and left hypochondriac regions. There was no diminution of the liver dulness. The patient had not vomited since the beginning of the attack. As the symptoms and signs were strongly suggestive of perforation she was removed to the Bradford Infirmary for an exploratory abdominal section to be performed. The operation, which lasted one hour, was performed fourteen hours after the onset of the acute symptoms. Ether having been administered, a median incision five inches long was made above the umbilicus. On opening the peritoneum some bubbles of gas escaped. There was no distension of the intestine or fluid in the peritoneal cavity. The stomach was drawn to the surface, and on its anterior aspect near the cardiac end a small opening the size of a crowquill was seen. Through this the mucous contents of the stomach escaped. The perforated part was drawn into the opening and the abdominal cavity packed with folds of Gamgee tissue. The edges of the opening in the stomach were pared with a knife and an attempt made to bring the edges together with catgut sutures. The stitches cut through the softened tissues, so a fusiform piece of the stomach wall, including the original opening, was removed with scissors. The margins of the enlarged opening were readily brought together by a continuous catgut suture. The serous layer was then inverted and a second row of continuous fine silk sutures applied. Finally, the omentum was turned up to cover the anterior surface of the stomach and fixed in position by a few silk sutures. The pads were removed and the peritoneum thoroughly cleansed by sponging. Two long glass drainage-tubes were inserted, the lower ends dipping into the pouches above the right and left kidneys. The abdominal wall was brought together with silkworm gut sutures. On the following day the patient had recovered fairly well from the shock of the operation. She had vomited once during the night, but the vomit contained no blood. A considerable amount of bloody serum was pipetted from the glass drainage-tubes. On the second day after the operation, as these caused considerable discomfort, they were replaced by rubber tubes. The rectal feeding, which had been effectual since the operation, was discontinued, as the enemata were not retained. Small quantities of food and stimulant were given by the mouth and retained. From this time the condition of the patient varied from day to day. There was no abdominal pain or distension; food was taken without discomfort, and the bowels were moved naturally. The tongue, which had remained red at the tip and margin, became drier and more thickly furred. A small stitch abscess formed at the upper part of the wound. The patient gradually became weaker, the symptoms of general peritonitis became more defined, and she died rather suddenly on Jan. 11th, 1895, the eleventh day after the operation. At the post-mortem examination the abdomen was found to be distended with sero-purulent fluid, which was localised by adhesions below the left arch of the diaphragm and in the pelvis. The small intestines were injected and glued together by flakes of plastic lymph. The stomach, which was covered in front by the adherent omentum, was considerably narrowed where the portion had been excised. The mucous membrane was in good apposition, and the peritoneal surfaces firmly adherent, no leakage having occurred. One of the inner row of stitches was seen in the stomach. The outer row was quite concealed by plastic lymph. Near the pyloric end the mucous membrane was thinned over an oval area with a raised margin, showing a second cicatrised ulcer.

Remarks by Mr. HORROCKS.—The previous history of epigastric pain and vomiting occurring in an anæmic woman was strongly suggestive of gastric ulcer even when blood had not been detected in the vomit. Perforation of the ulcerated stomach wall was indicated by the severe and sudden symptoms following the ingestion of the hot fluid. This was confirmed by the persistent localised pain, increased by any movement, by the constant contraction of the abdominal muscles ("guard action"), and the slow but steady increase in the pulse-rate. The natural position of the liver dulness is explained by the fact that the escaped air and mucous fluid were localised in the hypochondriac region and not generalised in the abdominal cavity. It was suggested before the operation that the case was one of acute gastric ulcer without perforation. This idea seemed negatived

Digitized by Google

by the severe character of the onset, the general hypochondriac dulness, and the acute pain, which was not localised over the stomach, but generalised over the region. The great increase of pain caused by twisting the trunk could hardly be caused by gastric ulcer. The amount of stomach wall removed depends on the size of the ulcer. It would probably expedite matters if the perforation was enlarged sufficiently to admit the tip of the finger. Flushing the peritoneal cavity with hot sterilised water seemed contra-indicated in this case, as the extravasation was not considerable in amount and was quite localised. It seemed reasonable to suppose that the peritonitis would remain localised if provision was made for the escape of the serous secretion. The time required for further section of the abdominal wall, flushing of the peritoneal pouches, and the insertion of a pelvic drainage-tube would have greatly increased the shock of the operation. As events proved, the peritonitis set up by the extravasated contents of the stomach was not localised by plastic lymph, so that the more severe procedure would probably have been better.

Medical Societies.

OBSTETRICAL SOCIETY OF LONDON.

Height of the Fundus Uteri above the Symphysis during the Puerperium.—Micro-organisms of Obstetrical and Gynæcological Interest.—Exhibition of Specimens.

A MEETING of this society was held on Oct. 2nd, Dr. F. H. CHAMPNEYS, President, being in the chair.

Dr. W. S. A. GRIFFITH and Dr. T. G. STEVENS contributed a paper entitled "Notes on the Variation in Height of the Fundus Uteri above the Symphysis during the Puerperium, the Conditions which influence this, and the Practical Conclusions which may be drawn from such Observations." It demonstrated the importance of recording by measurement "charts of involution" during the puerperium. It was for the most part drawn up by Dr. Stevens, and was the result of observations by Dr. Griffith and Dr. Stevens at Queen Charlotte's Lying-in Hospital. The method of measurement was first described, with the precautions necessary to avoid errors, and the method of recording the measurements on the ordinary temperature charts. The measurement is the height of the middle of the fundus above the symphysis. The sources of error are: (1) distension of the bladder; (2) distension of the rectum; (3) distension of the small intestines; (4) prolapse of the uterus; (5) abnormally high uterus; (6) unusual bulk of uterine muscle; (7) retroversion of the uterus; and (8) excessive lateral obliquity of the uterus. The pathological conditions which interfere with the involution of the uterus, and therefore with the descent of the fundus, are: (1) retention of portions of placenta and membranes and of blood-clots and lochia; and (2) putrid decomposition within the uterus. (There have been no septic cases to study.) Charts illustrating normal involution and its variations and pathological conditions were given, and their value in indicating, even before any rise in temperature, putrid decomposition was demonstrated. Reference was made to the works of Serdukoff[1] and Barbour.[2]—Dr. MCCANN wished to mention as a source of error in such measurements as those made by Dr. Griffith and Dr. Stevens marked anteversion of the uterus. With regard to the influence of suckling he had found that in women who had no milk involution was rapid, while in those who had milk and nursed their children involution was rapid for the first few days, the rapidity diminishing later, probably owing to the stimulus from the breasts decreasing. The effect of prematurity of labour as a cause of delayed involution was noted, and prolonged labour delayed involution for the first days. It was important to determine on what day the uterus became a pelvic organ, for on this rested to a large extent our opinion as to when a puerperal woman should assume the erect posture. Text-books stated that a patient ought not to leave her bed before the tenth day. Dr. McCann thought that a more scientific method was to investigate the position of the uterus before giving an opinion. He gave some statistics showing the days on which the uterus became pelvic in primiparæ and multiparæ respectively.—Dr. STEVENS said, in reply, that with regard to Dr. McCann's query as to extreme anteversion being a source of error in measuring the uterus, the dorsal position assumed for measuring purposes would tend to correct that displacement unless the anteversion were so extreme as to make the fundus lie entirely behind the symphysis pubis.—Remarks were made by Dr. GRIGG and Dr. GRIFFITH.

Dr. G. D. ROBINSON read a paper on Certain Micro-organisms of Obstetrical and Gynæcological Interest. He pointed out that in fatal cases of puerperal sepsis the streptococcus pyogenes is constantly found in the blood and tissues, and mentioned some of the circumstances which cause increase or diminution of virulence in this organism. Normally, after labour the uterine cavity was known to contain no microbe; but in cases of puerperal sepsis many micro-organisms of different sorts were found both in the uterine cavity and in the substance of the decidua. Of these only the streptococcus pyogenes appeared to be able to pass through the uterine walls along the veins and lymphatics, and so to cause a general infection. This microbe might in these cases cause death without producing any obvious lesion, and three cases were cited in the paper. Much more frequently the streptococcus set up suppuration in various tissues. Sometimes this microbe produced false membranes on the peritoneum or genital tract, with or without suppuration. Two cases were cited. Lately in some cases of phlegmasia dolens the streptococcus pyogenes had been found in the clots plugging the veins of the uterine walls and broad ligaments (more rarely in the clots in the iliac veins) and even infiltrating the vein wall itself. The supposed connexion of the bacillus coli communis with various inflammations (usually suppurative) was next pointed out, and a case was quoted in which a woman four months pregnant had intestinal obstruction from retroversion of a gravid uterus. Abortion occurred four days after reposition, and was followed in a few hours by fever and diarrhœa, which continued until the death of the patient five days later. During life pure cultures of the bacillus coli communis were obtained from the uterine discharge, and after death these were obtained also from the uterine cavity, peritoneum, and blood of the heart. Attention was next drawn to the gonococcus, its appearance as seen in gonorrhœal pus or in pus culture, its relation to gonorrhœal discharges, and the situations in which it had been found.—The PRESIDENT said that the paper was valuable as a summary of the present state of knowledge of a subject which most obstetricians have to take second-hand. One fact, with regard to the comparative impermeability of the decidua to micro-organisms, struck him as being important practically. It might not always be safe to curette the uterus when its contents were septic. In one such case within his own knowledge infection seemed to follow curetting, and a fatal result ensued.—Dr. C. H. ROBERTS asked Dr. Robinson if he knew the exact clinical appearance in the cases of white leg referred to in the paper, for the term "white leg" was made to include many forms. Dr. Roberts believed that the definite white brawny legs, with a very early onset of symptoms, and often with distinctive pelvic signs (parametritis &c.), were generally septic, while the commoner thrombotic leg came on generally later—viz., about the tenth to the twelfth day. He believed that high temperature did not necessarily mean sepsis. He also asked Dr. Robinson if anything was known of cultivations of the micro-organisms found in the brawny legs, and whether the streptococcus pyogenes was invariably found. He suggested that the bacillus coli communis was the cause of some cases of suppuration in ovarian tumours and extra-uterine sacs, which, on account of some reason for lowered vitality, became permeable to these organisms. If the streptococcus pyogenes were the only organism which had the power of penetrating the deeper layers of the uterus and the lymphatics, he thought that the early removal of the superficial layers by curetting should be attempted, combined with the antiseptic treatment of the uterine cavity.—Remarks were made by Dr. GRIGG and Dr. MCCANN.—Dr. ROBINSON, in reply, said he was unable to give any information as to the colour of the skin in the fatal cases of phlegmasia dolens, as this point had not been noted in the report. He thought that culture experiments made during life would be of no value, since it had been demonstrated that the secondary clots in the affected limbs rarely contained streptococci even in those fatal cases of the disease in which numerous

Digitized by Google

organisms were found in the primary clots and walls of the vessels. He had experienced the usual difficulty in separating the gonococcus from other microbes. According to his experience, the best method of doing this was by making plate cultures with a mixture of blood serum (human, ox, or horse) and agar-agar in the manner recommended by Wertheim and others.

Dr. WILLIAM DUNCAN showed specimens of Ruptured Tubal Gestation and Double Pyosalpinx complicating Pregnancy.

The PRESIDENT announced that the next meeting of the society would be made special, for the purpose of considering some recommendations of the Council regarding the society's laws.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

President's Address.

A MEETING of this society was held on Oct. 4th, Mr. A. SYMONS ECCLES, M.B., President, being in the chair.

Mr. KEETLEY moved a vote of condolence with Mme. Pasteur.

The PRESIDENT gave an address on the Advantages of Oxidation. It was remarked that a large portion of the oxidation processes occurred in the muscular system, and mention was made of the series of changes taking place in an active muscle, the sense of weariness being attributable to the accumulation of incompletely oxidised products. The grave consequences of partial arrest of oxidation processes were alluded to and stress laid on the presence in the system of leucomaines as a result, leading in some cases to a morbid condition which might best be termed "leucomainæmia." Reference was made to the work of Bouchard and others, and it was pointed out that in chlorosis, gout, &c. there was evidence of insufficient oxidation with excess in the urine of leucomaines and other products of incomplete oxidation. The train of symptoms generalised under the term "neurasthenia" were attributed to suboxidation. The method of von Poehl for the detection of leucomaines in the urine was described. It was shown that in melancholia &c. the symptoms varied *pari passu* with the amount of precipitate by von Poehl's process. The parallelism between the prodromata of acute fever and some of the symptoms of functional neuroses was attributed to like causes being in operation, though not of common origin. Comparison was drawn between symptoms of cinchonism and those of coprostasis, the poisons in both interfering with the oxidation process. It was suggested that much of the value of animal extracts might be assigned to their potency as oxidising agents. The value of exercise and other therapeutic means for promoting oxidation was detailed and illustrated by the narration of cases.

Dr. LAUDER BRUNTON laid stress on the value of apparently theoretical observations, and pointed out that many of Pasteur's most practical results arose therefrom.

Dr. CAMPBELL POPE made some remarks and the PRESIDENT briefly replied.

KIDDERMINSTER MEDICAL SOCIETY.

So-called Hermaphrodite — Exhibition of Cases and Specimens.—Intestinal Obstruction.—Osteotomy.

A MEETING of this society was held on Tuesday, Sept. 17th, Mr. D. CORBETT being in the chair.

Mr. J. L. STRETTON read notes of a case of So-called Hermaphrodite. A man aged sixty-seven years was born in a small village and pronounced a female; he was brought up accordingly and still believes that he is a woman. The condition of the genitals is one of hypospadias, the under part of the urethra being absent from the orifice to the junction of the penis and scrotum, where the outlet is now situated, otherwise he is quite naturally formed and but for regular shaving would have a well-marked beard and moustache. He asserts that he has never experienced any sexual appetite, and that he has lived alone in a hovel and worked in the fields. He is at present an inmate of one of the female wards of the Kidderminster Workhouse by direction of the guardians and the local inspector, who still maintain that he is a woman, and the Local Government Board see no reason to interfere.

Mr. P. E. DAVIES exhibited the Kidneys from a case of Purpura, which showed numerous hæmorrhages. The boy, who was aged five years, was admitted into the Children's Hospital in a very exhausted condition and rapidly became comatose, dying twenty-four hours later. The urine was normal, and the necropsy showed no change in the brain.—Mr. W. MOORE remarked on the rarity of coma in this disease, and Mr. KITSON mentioned that several cases of purpura had recently occurred in the same locality as this one, two of them in the same house.

Mr. J. L. STRETTON read notes of a case of Intestinal Obstruction in a youth aged seventeen years. There was no history of any definite diseases, no traumatism, and no history of rupture. He had had pain off and on about his "stomach" since childhood. Last Easter he had a severe attack of abdominal pain and sickness, but no obstruction, and the vomit was not fæcal. He was laid up for six weeks and has remained well until the present attack. On Aug. 28th he was attacked with severe pain while at the watercloset; he passed a hard-formed motion, the pain continued, and he vomited. The following day the vomit was fæcal. His medical man treated him with hot fomentations and injections, with no effect. The patient lies on his back with the knees drawn up, the breath has a fæcal odour, and the pulse is 84. The tongue is furred and moist. The abdomen does not move on respiration, it is slightly distended, and there are no signs of hernia. There is a feeling of resistance about the right iliac region, and it is dull on percussion. Mr. J. L. Stretton opened the abdomen in the middle line; no fluid escaped, and on introducing the hand a band was at once felt and divided. There were several hard lumps in the large intestine, near the seat of obstruction, and the bowel was glued to the anterior abdominal wall by recent adhesions. Owing to the state of the patient the operation could not be prolonged. He was comfortable on the following day, and the vomiting ceased, but he became more collapsed and died in the evening after a severe attack of vomiting. No fæces or flatus had passed. The necropsy twelve hours after death showed that the abdominal wound appeared to be healthy, and that there had been no recent peritonitis. The root of the band was about the diameter of the little finger; it had extended from midway above the transverse colon (attached to its mesentery), across it, bending it down, and was attached to the mesentery of the ileum near the cæcum. There were several recent adhesions between the colon and the abdominal wall. The obstruction had been relieved by the operation. The case was of interest on account of the extreme rarity of the condition. Treves speaks of it as a pathological curiosity.

Dr. EVANS showed a girl aged fourteen years, from whose right leg the whole length of the diaphysis of the tibia had spontaneously exfoliated; it was only held *in situ* by a small band of granulation tissue and was easily removed. She has made an excellent recovery and has a useful limb, new bone being formed. A water-colour drawing of the condition was exhibited.

Mr. J. L. STRETTON read a paper on Osteotomy, with notes of one hundred and eight operations.

YARROW HOME FOR CONVALESCENT CHILDREN, BROADSTAIRS.—We understand that this home, the formal opening of which lately took place, is now in perfect working order and gradually filling up. The trustees are prepared to receive applications for admission of children, which should be addressed to the Secretary of the home at the London office, 73A, Queen Victoria-street, E.C. It should be understood that the institution is intended to benefit the children of middle-class or professional persons in adverse circumstances. The limits of age for boys is from four to fourteen and for girls from four to sixteen.

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—St. Bartholomew's Hospital is specially rich in endowed scholarships, and five of these are awarded to students just entering upon their medical studies. The competition, which was held on Sept. 25th and following days, has resulted in the following awards:—1. Scholarship of £75 in Biology and Physiology for students under twenty-five years of age: C. S. Myers, B.A., Caius College, Cambridge. 2. Scholarship of £75 in Chemistry and Physics for students under twenty-five years of age: J. S. Williamson, 3. Scholarship of £150 in Biology, Chemistry, and Physics for students under twenty years of age: R. C. Bowden and R. H. Paramore (*æquales*). 4. Preliminary Scientific Exhibition of £50 in Biology, Chemistry, and Physics for students under twenty years of age: J. C. M. Bailey. 5. The Jeaffreson Exhibition of £20 in Classics and Mathematics: H. A. Kellona-Knight.

Reviews and Notices of Books.

The Cell: Outlines of General Anatomy and Physiology. By Dr. OSCAR HERTWIG, Professor in the University of Berlin. Translated by M. CAMPBELL, and edited by HENRY JOHNSTONE CAMPBELL, M.D. Lond., Demonstrator of Physiology in Guy's Hospital. With 168 Illustrations. London: Swan Sonnenschein and Co. 1895. Pp. 368.

THE immense progress that has been made during the last half-century in our knowledge of histology, and the vast importance of the cell in every department of biology and in every function of life, render it extremely desirable that a full and comprehensive account of the nature of these elementary units of the plant and animal bodies, embodying the results of the most recent researches, should be given from time to time by a competent writer. In Germany this has been frequently and well done, as by Schleiden, Schwann, Kölliker, von Mohl, Virchow, and many others; but in this country we can only point to the writings of Beale, Huxley, Cleland, and Turner for such a comprehensive account, and we are greatly indebted to Mr. Henry Johnstone Campbell for having translated so ably the admirably written work of Dr. Oscar Hertwig, which may be regarded as representing the present standpoint of our knowledge respecting the structures and functions of the cell. The author commences with a short history of the cell and of the protoplasmic theory, in which he points out the modifications that have taken place in our definition of the word "cell." Grew and Malpighi were the first who noticed the cubical or polygonal spaces in plants; Schleiden dwelt upon the importance in plant cells of the nucleus, a structure that had previously been discovered by Robert Brown in his researches on orchids; whilst Schwann, with much labour, extended to animal structures the same conceptions that had already been generally accepted in regard to plants. By these well-known writers and teachers the cell was defined as a small vesicle with a firm membrane enclosing fluid contents and a nucleus. The study of the vegetable cell by von Mohl led him to lay much stress upon the slimy contents of cells, to which he first applied the term "protoplasm," though the word itself had been coined by Purkinje, and he observed the spontaneous movements which it was capable of performing. By degrees, with the more precise methods of microscopical observation, it was noticed by many investigators, but especially by Bischoff and Kölliker, that animal cells were very commonly unprovided with a membrane, and that which the older observers regarded as the most essential part of the cell — the cell membrane—was really of minor importance. Schultze and de Bary next proved that the protoplasm of plants and animals and the sarcode of the lowest organisms are identical; and thus the modern definition of a cell has come to be that it is "a little mass of protoplasm which contains in its interior a specially formed portion — the nucleus."

In the next chapter Dr. Hertwig describes the chemico-physical and morphological characters of the cell as above defined. Our chemical knowledge of protoplasm is very unsatisfactory; indeed, it is not to be regarded as a chemical, but as a morphological, conception. It is probably composed of a large number of different chemical substances united in the form of minute particles into a highly complex structure. It is alkaline, contains a large percentage of water, and the elements carbon, hydrogen, oxygen, nitrogen, and sulphur, with many salts. Examined with very high powers of the microscope, it presents certain appearances of structure. But these are so obscure that there is great difference of opinion in regard to their nature—some, as Frommann and Klein, holding to a framework theory, seeing a network of fibrils in the interstices of which fluid is contained; others, as Bütschli, having adopted a foam or honeycomb theory, comparing it to an emulsion; others, again, as Flemming, maintain a "filament" theory, in which the substance of protoplasm is regarded as composed of a thread substance — mitoine — and an interfilamentous substance—paramitoine; and, lastly, a "granuls" theory is held by Altmann, the granula being exceedingly minute creatures or bioplasts swimming in a gelatinous or "intergranula" substance.

The vital properties of the cell are considered under the respective headings of the Phenomena of Movement; the Phenomena of Irritability; Metabolism and Formative Activity; and Reproduction. The several kinds of movement are true protoplasmic movements; ciliary or flagellar movements; the movements of the pulsating vacuole; and the passive movements and changes of shape that the cell exhibits. In regard to the contractile vacuoles Dr. Hertwig agrees with Schwalbe and Engelmann that they possess contractile walls, though they are not clearly defined from the rest of the protoplasm. But he differs from Bütschli—who thinks that they only represent a drop of water in the protoplasm—in believing that they have a definite existence, in proof of which he points to their constancy, to the presence of radiating canals, and to other circumstances. The phenomena of irritability include those of muscular movement, in speaking of which the author remarks that, whilst the earlier natural philosophers held that it was the expression of a special vital force only seen in organised nature, modern science has discarded the theory of vitalism, considering it to be a very complicated chemico-physical phenomenon, differing only in degree from other chemico-physical phenomena of inanimate nature—that is to say, "the external stimuli come into contact with a substance very complex in structure, an organism which is an exceedingly complicated material system, and in consequence they give rise to a series of very complex phenomena." He adds, however, a word of warning that we should not fall into the very common mistake of trying to explain vital processes "as being due directly to mechanical causes" in consequence of their analogy to many phenomena seen in inanimate objects.

A very good section is devoted to the internal plasmic products of cells under the heading of Morphology of Metabolism. It includes the consideration of cell-sap, fat, glycogen, starch, mucin and albuminates, crystals and crystalloids, and, amongst others, bodies named trophoplasts. These last occur as constantly as the nucleus and possess great functional independence. They are of great importance in the nutrition of plants, for the whole process of assimilation and the formation of starch take place in them. They are small ovoid bodies composed of a substance similar to, but differing from, protoplasm. They are easily destroyed by water, but may be fixed by iodine or by strong picric acid. They often exist in great numbers in a cell and may actually change their form. Through their agency and derived from them the starch and chlorophyll granules are formed. Recent researches have shown that chlorophyll granules are capable of undergoing great changes in shape, offering to direct sunlight a small surface and to diffused daylight a large surface. Another remarkable internal plasmic product is the nematocyst, a weapon of attack possessed by the Cœlenterata, as many bathers during the summer season of this year found to their cost. The external plasmic products are cell membranes, cuticular formations, and intercellular substances, to each of which a few paragraphs embodying the results of the most recent investigations are given. The latter part of the book is occupied with the consideration of the phenomena of Reproduction. The concluding chapter is devoted to

Digitized by Google

the question of Heredity and the Relation of the Cell to the Elemental Germ.

There is an excellent bibliography appended to each chapter, and there is a good index. The book is very well got up, and the illustrations are numerous, well selected, accurate, and excellently printed. It occupies a space in literature which much needed to be filled.

Forensic Medicine and Toxicology. By J. DIXON MANN, M.D. St. And., F.R.C.P. Lond., Professor of Medical Jurisprudence and Toxicology in Owens College, Manchester; Examiner in Forensic Medicine in the University of London and in the Victoria University; and Physician to the Salford Royal Hospital. London: Charles Griffin and Co. 1893. Pp. 639.

WE regret that through inadvertence the above important work by Professor Dixon Mann has not previously received editorial review at our hands. From the important medico-legal posts held by the author he has unusual opportunities for acquiring practical experience of his special subject and of ascertaining the wants of students and practitioners. On looking through the pages of his book the reader will recognise the lucid manner in which the facts are stated and the ready way in which the deductions are drawn and formulated. Chapter I. deals with the coroner's and magistrates' court and with assizes. The procedure in the coroner's court is on the whole well discussed, but we fail to notice any mention of the following facts: that the coroner has magisterial functions which enable him (1) to commit for murder or manslaughter; (2) to order an exhumation of a body on his own initiative; and (3) to take hearsay evidence which would not be admissible before a magistrate or at an assize court. The counsel to medical witnesses for their guidance in courts of law is admirably expressed. The chapter on Cadaveric Rigidity is clearly discussed, and due attention has been given to the chemical changes in muscle incidental to their stiffened condition.

Speaking of the guaiacum test for blood, the author does not explicitly state the necessary check experiment when filtering paper is used to demonstrate the stain. Some varieties of this paper give a distinct blue reaction with the reagents alone, consequently the latter should be used with and without the object to be tested. Regarding the carbon-monoxide-hæmoglobin spectrum we do not find mention of the fact that it may be readily observed after a considerable lapse of time. In one case it was unimpaired at the end of two months. Criminal responsibility in its relation to insanity is dealt with in a masterly fashion. Space does not permit a lengthy review of each section of Professor Mann's work, but we may say generally that the arrangement of the subjects is good. The diction leaves nothing to be desired. The author marshals his facts in simple but imposing order and draws his deductions with singular skill. The letterpress is bold and distinct. An increase in the number of illustrations is, perhaps, desirable. We can strongly recommend the work to students and practitioners of medicine.

The Human Flower: a Simple Statement of the Physiology of Birth and the Relations of the Sexes. By ELLIS ETHELMER. Third Edition, further enlarged and revised. Mrs. Wostenholme Elmy, Buxton House, Congleton. 1895.

WE are told in the introduction addressed to parents that the purpose of this small treatise is "to give in plain and inoffensive terms a short and simple account of the circumstances attendant upon the birth of human beings into the world." In the opinion of the author, it is so written that it may be "fittingly placed in the hands of sons or daughters at an age when their growing intelligence seeks to know the origin of their being." In order to meet the various ages of readers the first two chapters (says the author) are written "in as simple words as are consistent with accuracy"; and personally the author assures us that he (or perhaps we should say "she") "would not hesitate to entrust the book to a child of however tender years." We live in an age when there is a tendency to regard almost everything as a matter of opinion; and, in the author's opinion, it is a desirable thing to set boys and girls to read such a book as the one before us, in which the male and female organs of generation and their uses are systematically described. We cannot ourselves agree with the author in this matter. There is, no doubt, as is said here, a strong analogy between the reproductive process in plants and animals, or, to be more precise, between the reproductive process in plants and in man. But there is a considerable difference between studying that process in the vegetable kingdom and studying it in man with, as we have said, a precise description of the structure and functions of the organs of generation in man. We can see no objection to the study of botany among young people, girls or boys, and we should think that the analogy between the reproductive process in plants and in the animal kingdom would suggest itself to their minds quite sufficiently. The author, we think, rather loses sight of the enormous differences between plants and human beings, and makes too little allowance for the part played in mankind by the emotions. We can easily imagine that a great deal of harm might result from a boy being set to read the description given of the generative apparatus in the female, and similarly from a young girl being made to read the description of the corresponding organs in the male. Curiosity, and the desire to test the accuracy of the description, might easily occasion much harm—far more, it seems to us, than any good that the knowledge in question would be likely to do to its possessor. We do, in fact, agree with the advice here quoted from Ruskin as to the education of a girl, which appears to us to be the exact opposite of the definite and precise teaching recommended by the author. "Let her *loose* [the italics are ours] in the library, I say, as you would a fawn in a field. It knows the bad weeds twenty times better than you, and the good ones, too, and will eat some bitter and prickly ones, good for it, which you had not the slightest thought were good."

Annals of Ophthalmology and Otology. Vol. IV. January, 1895. No. 1. St. Louis, Missouri: James Parker.

THIS number contains an account of various methods of treating corneal opacities by Dr. David Dennis of Erie, Pennsylvania. He obtained great success by carrying out a plan devised by Dr. Alleman which consists in attaching to the negative pole of a battery, with a current of one-quarter to half a milliampère, a small silver electrode with concave contact surface, in which, for the sake of surer contact, a globule of mercury is made to adhere. The time of contact was about one minute. In one instance the current was alone employed; in others pressure inunctions and yellow oxide of mercury, and in another pressure inunctions alone. Dr. J. Thorington has some sensibly written observations on Skiascopy. Dr. Joseph Willetts discusses the cause of the halo or rainbow symptom in glaucoma, which he attributes to stasis and œdema of the cornea. Dr. John Ball contributes an article on the treatment of traumatic cataract attended by rapid swelling of the lens. He advocates the removal of the lens through a section made with Graefe's knife in the sclero-corneal junction, extending from one-third to two-fifths of the corneal circumference, without iridectomy, and careful removal of the softened lens substance. Mr. Charles Prentice solves a problem in cemented bifocal lenses by the prism diopter. A case of retinitis pigmentosa is reported by Dr. Dunbar Roy of Atlanta, Georgia; one of

Digitized by Google

fibroma of eyelids by Dr. George Goode of Cincinnati; one of embolism of the inferior branch of the central retinal artery by the same author; one of detachment of the retina by William E. Bruner of Cleveland, Ohio; and there is a paper on the ripening of immature cataract by direct trituration by Dr. Bourne Bettman of Chicago. In the department of otology Dr. Walter Park of Harrisburg, Pennsylvania, describes an interesting case of acute purulent inflammation of the middle ear with two attacks of double optic neuritis, no mastoid complications, frequent delirium, two operations, and recovery; Dr. H. A. Alderton of Brooklyn, New York, gives a careful study of the influence of affections of the upper air tract upon the ear, with numerous statistics; Dr. Otto Koerner of Frankfort-on-Maine contributes the details of a case of tuberculosis of the temporal bone with extension to the adjoining brain; and Dr. Walter Park of Harrisburg, Pennsylvania, has devised a new and more convenient instrument than a Politzer air-bag.

Medical Electricity. By H. LEWIS JONES, M.A., M.D., Medical Officer in charge of the Electrical Department in St. Bartholomew's Hospital. Being the Second Edition of *Medical Electricity*, by W. E. STEAVENSON, M.D., and H. LEWIS JONES, M.D. London: H. K. Lewis. 1895. Price 10*s.* 6*d.*

WE gladly welcome the second edition of this valuable work. Electricity is becoming day by day more generally recognised by members of the medical profession to be an agent of great value for diagnostic as well as therapeutic purposes. Many, however, who are anxious to use it are somewhat hazy as to the various methods of electrification, as to the results they expect or wish for, and as to the management and care of sources of electricity, such as batteries or induction machines, and to all such this book will be of great use. In this second edition the general plan of the first has been adhered to, but some of the early chapters have been simplified, notably by the omission of many recondite mathematical formulæ. The various sources from which electricity can be obtained for medical purposes are very fully set forth. We are glad to see that Dr. Lewis Jones has avoided using the eponymous words galvanism, faradaism, &c., substituting the far better titles currents from cells or from the induction coil. One specially valuable feature in this edition, which was not present in the first, is the set of illustrations representing the appearances in paralysis of various muscles. We may refer especially to Figs. 71 and 72, representing paralysis of the trapezius and serratus magnus respectively. The chapter on Electrolysis and its various applications is very clear and practical, especially with regard to the treatment of nævi. We have no hesitation in recommending this work as most valuable to the busy practitioner: it does not pretend to take the place of the large treatises of Erb and Beard and Rockwell, but as a practical handbook it will be found exceedingly useful.

The Science and Art of Bread-making. By WILLIAM JAGO, F.I.C., F.C.S. London: Simpkin Marshall and Co., Limited. 1895.

IT is only within the last twenty years that the operations concerned in the making of bread have been studied and understood—since, in fact, modern experimental enquiry threw light upon the nature of fermentation, of the action of yeast, and the functions of bacteria. Not the least important aspect of the application of scientific methods is that *pari passu* with the advance of knowledge on the points of manufacture the necessity of cleanliness came to be understood, as well as of the adoption of rigid sanitary principles. The worth of a book of the kind before us is therefore strikingly manifest, and those engaged in the industrial operations with which it most exhaustively and thoroughly deals, and who are interested in the scientific aspect of the question, owe Mr. Jago a tribute of praise and gratitude. It is written within the reach—of the baker's man, we had almost said—but certainly of the master baker, who, if he be not acquainted with the elementary truths of chemistry, and especially those concerned in bread-making, is presented with them in a way which, if he have any intelligence at all, he will easily and eagerly grasp. Thus from introductory principles and a description of the principal chemical elements and their compounds, inorganic and organic, he is brought to understand the composition of wheat and wheat flour, the carbohydrates, the proteids, enzymes, yeast fermentation, &c., until in the sixteenth chapter the subject nearest his interest—bread-making—is admirably treated. This chapter deals specially with matters of primary importance to the practical baker. This is evident when we find it is divided into headings as follows: various bread-making methods, a review of panning fermentation, sour bread, faults in bread, leavened bread, baking powders, flour blending, &c. More or less technical are the chapters which follow on special breads and bread-making processes, bakehouse designs, the machine bakery and its management, till a description of analytical apparatus essential to the examination and valuation of bread leads up to the commercial testing of wheats and flours, and excellent and clearly written chapters on the determination of mineral and fatty matters, of soluble extracts, acidity, proteids, the estimation of carbohydrates, and so forth.

The analysis of bread in particular is summed up in Chapter XXV., and the methods for the detection of adulteration—which happily there is reason to believe is rarely practised now—are given in Chapter XXVI. In the directions for the estimation of sugar the author has probably inadvertently omitted to mention the Pavy modification of Fehling's method, which offers very distinct advantages, since when the reaction is complete the solution becomes clear and colourless, while with the Fehling solution it is difficult to tell the precise point when the whole of the copper is precipitated owing, as not infrequently happens, to the suboxide not separating readily. In some experiments on the effect of "alumed" bread upon digestion the author shows that alum retards proteid digestion to about half the rate which obtains in its absence, and that the use of "alumed" baking powder is as injurious as that of alum alone, so that the evil of a definition which in the Food and Drugs Act does not condemn, according to a notorious and recent decision in the High Courts, the use of alum in baking powder, because it cannot be regarded as a food, is accentuated.

We congratulate the bread-making industry on possessing such a valuable work of reference. The interest of the subject is, however, not theirs alone, and it is evident, from the stock of valuable material with which, as we have indicated, it exhaustively and admirably deals, that analysts, sanitarians, medical men, and others will also gather distinct profit from a perusal of its pages.

CHOLERA.

THE official returns from St. Petersburg show that 51 cases and 19 deaths from cholera occurred in the province of Podolia, and 7827 cases and 3085 deaths in the province of Volhynia during the first fortnight of September. The district of Berditcheff in the government of Kieff is also officially declared to be infected.

LIEBIG'S EXTRACT OF MEAT COMPANY'S BEEF PEPTONE (EXTRACTUM CARNIS).

(LIEBIG'S EXTRACT OF MEAT COMPANY, 6, FENCHURCH-AVENUE, E.C.)

WE have submitted this meat preparation to a somewhat extended analysis with most excellent results. As will be seen from the figures given below, it presents remarkable dietetic advantages, containing not only the vital principles of beef in a very highly concentrated form, but in an easily assimilable condition. In short, it is a peptonised meat compound in which the nourishing nitrogenous constituents of meat, as albumin, fibrin, &c., have been reduced to a readily digestible state, while the important stimulating principles (chiefly crystalline bases) have also been retained. Its composition, according to our analysis, is as follows: water, 28·02 per cent.; peptoniferous matters, 45·28 per cent. (consisting practically of equal amounts of albumose and true peptone); gelatine, 3·65 per cent.; albumin (coagulated on boiling and on slightly acidifying with acetic acid), 2·00 per cent.; crystalline meat bases, 11·98 per cent.; mineral matter, 9·07 per cent., containing 1·40 parts common salt, 0·07 part phosphate of lime, and 7·60 parts of phosphate of potassium. The total nitrogen amounted to 9·30 per cent. This analysis illustrates the importance of ascertaining in what form the proteids exist in preparations offered as nutrients. A meat preparation may appear to possess, so far as regards its total nitrogen, a high food value, but it might consist chiefly of gelatine, which bears no comparison, of course, in regard to food value with a similar proportion of albumose or peptone containing the same amount of nitrogen. The fact that the above preparation, for example, contains 9·30 per cent. of nitrogen conveys nothing as to its really nutritive character, but when the proteid matters are separated and estimated by chemical methods its worth as a nutrient becomes at once evident. This important aid to the differentiation of the kinds of proteids in peptonised preparations is largely due to the classic and well-known researches of Kühne and Chittenden and others. If reference be made to the above analysis it will be seen, not only what a powerful food this Liebig's new beef peptone is, but that the proteids have been so prepared as to be present under the best conditions for assimilation in the alimentary tract. Quite one half of the extract, in fact, consists of the products of peptonic digestion, while albumin, coagulable on boiling, which, together with water and salts, is able alone to support the vital processes, occurs in important quantity. The presence of a notable proportion of soluble phosphatic constituents is calculated to further add to the beneficial influence of this preparation upon nutrition. It is quite free from the unpleasant taste and odour which have hitherto largely detracted from the administration of peptonised meat compounds by the mouth, and contains no objectionable preservatives. Its composition is founded on an excellent physiological basis, indicating it to possess to an eminent degree all the requirements of a nitrogenous food, which, offering no difficulty to the digestive functions, must contribute very effectively as a nutrient in the repair and maintenance of the body tissues. The presence of a noteworthy proportion of crystalline meat bases adds to its value as a restorative and stimulant.

JEREZCONA WINE.

(HERTZ AND COLLINGWOOD, 4, SUSSEX-PLACE, LEADENHALL-STREET, E.C.)

As might be gathered from the name of this wine, it consists of a well-known mature sherry (of the famous Xeres district) in which the active constituents of cinchona bark are skilfully dissolved. It presents, therefore, real bitter and tonic properties in an agreeable form. That the wine is old and ripe is evident to the palate, the taste being, however, pleasantly and delicately bitter. A definite quantity of the alkaloids of cinchona bark was obtained on alkalising the wine and extracting with ether. These occur combined as hydrobromate, so as to minimise the disagreeable effects produced by ordinary cinchona preparations. The composition of the Jerezcona, apart from its medicinal characters, is indicated in the following analysis. Alcohol, by weight, 14·64 per cent.; by volume, 18·03 per cent.; proof spirit, 31·61 per cent.; extractives, 6·72 per cent.; mineral matters, 0·52 per cent. It is an obvious advance on the usual type of bitters.

1. GOLD PREPARATIONS (LIQ. AURI BROM. ARSENATIS, ETC.). 2. TANNOPUMILINE.

(ARTHUR AND CO., 69, BERNERS-STREET, OXFORD-STREET, W.)

Gold preparations have lately been advanced as remedial agents of distinct value. The bromide of gold, for instance, has been observed to exert a more powerful action on the psychomotor centres than the corresponding potassium salt, although the former contains nearly a fifth less bromine. Excellent results, it is stated, have also followed the use of bromide of gold in scleroses, and still more recently a solution of gold tribromide and of oxybromide of arsenic have been administered with marked benefit in locomotor ataxy. Specimens of "Liq. auri brom. arsenatis," as well as of "Liq. auri brom. arsen. mercuratis," have recently been submitted to us by the above chemists. The former is a combination of tribromide of gold ($AuBr_3$) with oxybromide of arsenic (AsOBr), and the latter contains in addition oxybromide of mercury (3 HgO, $HgBr_2$)—a combination which is said to be a specific for syphilitic tendency, producing, however, less salivation than the simpler mercurial salts. The care needed in order to get stable solutions of gold compounds is well known, and those before us are highly satisfactory in this respect, containing no excess of objectionable menstruum. The pure tribromide has been used, as our readers are aware, in epilepsy.

Tannopumiline is an interesting and apparently true compound of digallic acid with the terpene of the essential oil of pumilio pine. It has been found valuable in the treatment of perspiration of the feet and in dermatitis, for which affections it is declared to be superior to boracic acid and allied remedies. It is employed as a paint for chilblains, chapped hands, &c.; it dries rapidly and leaves a thin protective film. As might be expected, tannopumiline is not miscible with water. We can confidently commend the above preparations, not only on account of their novelty, but because they are prepared with care, are pure, and therefore admirably adapted for the purposes for which they are designed.

THE Canadian Medical Association has appointed the following gentlemen as officers for 1895-96:—President: James Thorburn, Toronto. Vice-Presidents: Prince Edward Island—James Warburton, Charlottetown; Nova Scotia—Wm. Tobin, Halifax; New Brunswick—W. W. White, St. John; Quebec—Hon. D. Marcil, Quebec; Ontario—Fife Fowler, Kingston; Manitoba—H. H. Chown, Winnipeg; North-West Territory—G. Brett, Banff; and British Columbia—R. E. McKechnie, Nanaimo. General Secretary: F. N. G. Starr, Toronto. Local Secretaries: Prince Edward Island—H. D. Johnson, Charlottetown; Nova Scotia—G. C. Jones, Halifax; New Brunswick—Wm. Christie, St. John; Quebec—J. G. McCarthy, Montreal; Ontario—John H. Mathieson, St. Mary's; Manitoba—W. J. Neilson, Winnipeg; North-West Territory—Geo. Macdonald, Calgary; and British Columbia—W. A. Richardson, Victoria. Treasurer: H. B. Small, Ottawa. The meeting in 1896 will be held in Montreal.

THE LANCET.

LONDON: SATURDAY, OCTOBER 12, 1895.

THE general practitioners of the country will be deeply interested in the series of articles which we are publishing headed "The Battle of the Clubs," giving details of a contest which must be fought out, and which, it will be seen, is not confined to our own country. Some time since we gave an account of a similar conflict in Germany. The present series of papers includes our special commissioner's description of a very interesting dispute between the Syndicate of Friendly Societies in Brussels and the medical profession, in the ranks of which there is great unanimity. Syndicates are the order of the day—"the individual withers and the world is more and more." We are of the number who believe greatly in individualism. Every member of the profession is placed occasionally in a position either to honour or to discredit the profession. It is the interest of the profession to have each member so conscious of this responsibility that under no circumstances shall he forget what he owes to the body corporate and to its traditions. He may temporarily suffer, or seem to suffer, in his individual capacity; but in the long run he is certain to gain. This is the point at which individualism and the *esprit de corps* meet, correcting each other's faults and coöperating in great lines of conduct which make ultimately for the good of all concerned. The charge of trades-unionism is one that need not weigh heavily on a body of men like the medical profession. We have never pretended as a profession not to have rules and traditions in which the individual was to be subordinate to the whole. If these rules and traditions have mainly and honourably had reference to questions of conduct they have not excluded questions of charge. Even honoraria are regulated by these same rules and traditions. It would be a grievous surrender of the interests of consulting practice if its junior members were to initiate consultation fees of less than the traditional minimum, which was supposed to be the least on which the dignity of the consultant class could be maintained. But he is almost more culpable who, in the sphere of general practice and for mere selfish reasons, takes an opportunity of profiting by the ungenerous demands of clubs or of private patients to reduce the modest remuneration of those who conduct general practice in its most arduous and exacting forms. No dread of the unreasonable charge of trades-unionism can excuse members of the profession for so acting or exempt them from the duty of denouncing those who so act. It is the privilege of the public and of its poorest members to have, not only medical advice, but the combined action of the profession in earnest consultation when urgency so requires. But there is a corresponding obligation on the part of the public and of those who administer great clubs for medical purposes to realise their obligations to the profession as a whole and to remember that they do not discharge these by beating down to the lowest terms and by "sweating" its youngest and its neediest members.

The articles recording the "Battle of the Clubs" which we are publishing from week to week afford us justification for thinking that the clubs and some of the public who have no claim to cheap attendance are dealing with medical men in a way that is ungenerous and unjust, and for approving of the conduct of the profession in various places when they stigmatise as opportunists those who try to supplant their brethren who are vindicating the just claims of medical service. The shabbiness of clubs is the more unreasonable because it coincides on the one hand with a great improvement in the wages of working men, and on the other with a considerable addition to the cost and length of medical education. The story is practically the same in every place where the state of matters has so far been disclosed—Cork, Brussels, Portsmouth, and Eastbourne. At Brussels there are about 450 medical men in practice, and 430 of them have joined what is called the Medical Syndicate. They have made it clear that their object is not so much to increase their rate of pay, but absolutely to refuse to attend rich men on the same terms as the labouring classes. Acting under the direction of this syndicate, twenty medical men in the service of the united clubs—the "Fédération des Mutualistes"—with exemplary discipline, resigned their posts, but in conformity with the requirements of the same authority continued to attend on grounds of humanity patients who were under treatment when the movement commenced. Eleven medical men took their place, only four of whom have proved effective. One of these was appointed chief medical officer at a high salary. The Medical Syndicate felt bound to disclaim him, and they did so with such completeness and effect that he apologised for his conduct and joined the Medical Syndicate. Our special commissioner wisely points out that in all these disputes it is necessary to appeal from the executive cliques by which the clubs are governed—often composed of the very classes objected to in clubs by the medical profession—to the whole constituency of the clubs—in other words, to public opinion. Working men are not naturally mean or likely to refuse their sympathy to those who are following their own example and making a united stand for proper terms. In his admirable account of the "Battle of the Clubs" at Portsmouth our special commissioner indicates with much clearness the injury to medical practice involved in the wide extension of the club system and in the coincident growth of a spirit of parsimony which, as we have said, is not natural to the mechanics of this country and which is especially unworthy of men whose weekly wages have increased of late years by 10*s.* a week. Formerly clubs were only meant for the accommodation of the bread-winner of the family, who was both willing and able to pay reasonable bills to his medical man for attending his wife and children. This was a far more satisfactory arrangement, not only for the medical man but for the people, who had thus the sense of privacy and independence in their medical relations. But now the demand is that the wives and children shall be attended on

Digitized by Google

club terms; and at Portsmouth there is a rate of pay which is simply disgraceful. The Portsmouth Dockyard Medical Benefit Society admits infants and juveniles as well as adults at the uniform rate of ½*d*. per week! For this sum, not only the actual attendance of a fully qualified medical man is expected, but all necessary medicines, leeches, dressings, bandages, splints, &c. This seems to us the most discreditable instance of sweating yet disclosed either by the General Medical Council's investigations or those of our commissioner. And unfortunately it is sought to raise it into a model to be imitated by other societies, including the Rechabites, who actually use their temperance as an argument for imposing similar or worse terms on their medical officer. The medical profession must consult its own dignity in regard to such facts. The mere publicity of them should be enough to bring about a reform. If not, the medical men of Portsmouth, who have formed themselves into a union, will have the sympathy of the profession in their claims for the establishment of a reasonable wage limit in clubs and for a more adequate recognition of the value of medical service generally.

The profession at Eastbourne, according to our commissioner, is acting with great ability and public spirit in fighting two medical aid associations which carry on the double business of insurance against sickness and insurance against death. It is found that assurance companies which aim at life insurance on a small scale find it much more easy to procure business when they can include a provision for sickness. Accordingly the profession at Eastbourne has had to encounter two big assurance companies—the Liverpool Victoria Legal Friendly Society and the Prudential Assurance Company—both acting virtually as medical aid associations, both resorting to canvassing, the canvassers being careless as to the exclusion of unfit persons and rather preferring those who can pay larger premiums for life insurance. The result has been a most creditable unanimity of the profession and the creation of the Eastbourne Provident Medical Association, formed by the profession itself and to which all its members are admissible. The staff of the Provident Association consists of nine medical men, while three medical officers of the Prudential Assurance Company have abandoned their connexion with that body and have brought over most of the members to the medical association of the profession. The Prudential office itself seeks to persuade its clients to join the Eastbourne Provident Medical Aid Association. The three officers of the National Medical Aid Company, working with the Liverpool Victoria Legal Friendly Society, have resigned their office and explained to their patients the advantages of joining the Eastbourne Provident Association. Practically the Eastbourne medical men have been rewarded for their firmness and union by victory all along the line. Let these examples of combined action be laid to heart in other places. Our commissioner will continue his researches, and we shall be glad, indeed, if the important articles which he is writing should help to place the claims of the profession in a clearer light before the working classes. We will try to think that he is in error in attributing to them the hardness and ungenerousness which they are so ready to attribute to employers of labour. The medical profession has, and must ever have, strong claims on their respect. It will not act harshly or hastily. But it is determined to act firmly and with self-respect.

AN able writer in one of the monthly magazines draws attention to what he calls the "gaps in evolution." The chief points insisted upon are the absence of any evolutionary doctrine to account for the origin of life, for the mode in which variations arise, for the first beginnings of mind, and for the fact that the actual transition of one species into another has never been proved. We are far from denying that these are weighty points, well worthy of the attention which evolutionists have been the first to bestow upon them, but we demur to the apparent conclusion of the reviewer that they are sufficient to warrant the rejection of evolution as a working hypothesis of the probable method of cosmic development. It is easy to show that there are *lacunæ* in the evolutionary theory which we cannot at present fill up, that much remains unexplained, perhaps inexplicable, and that evolution is still far from precise and complete demonstration. It is not so easy to point to facts that are in any way destructive of the evolutionary hypothesis, or to suggest any alternative doctrine which is not beset with even greater difficulties. Evolution leaves much unexplained—that is admitted; but we question whether there is any single fact in physics or biology which can be definitely regarded as fatally opposed to evolutionary theory, if we were able to take a sufficiently accurate and comprehensive view of all the facts of the case. Let us look at the difficulties suggested by the reviewer. Evolution throws no light on the origin of life. Scientific men hold as certain the axiom *omne vivum ex vivo*. Life as we know it always arises from antecedent life, and to allege that while this is so now, there may have been a time in the history of this planet when the living arose from the not living, is to advance a violent hypothesis contrary to all scientific analogy, and only intended to get rid of a glaring difficulty. We fully admit the force of this reasoning. The various hypotheses—such as the possibility that life might have been introduced to this planet by a meteorite or the like—that have been advanced to meet the difficulty have always struck us as singularly weak. We think it better to admit that the origin of life is from the scientific point of view an insoluble mystery—as insoluble as the origin of matter or of force; but we fail to understand how the admission of this difficulty is fatal to evolution. If evolution cannot explain the origin of life, what theory can? Is the doctrine of special creation, or whatever be the competing theory with evolution, in any better position? The assumption that life never began, but is eternal, is beset with greater difficulties than any that encompass evolution. Life as we know it always arises from antecedent life—in other words, we have no *scientific* ground for believing in life without origin and without cause. Such a doctrine is, we need not say, quite tenable by the theologian, but he cannot justify it on scientific grounds, and if he is wise he will not try to do so. The origin of life remains a mystery, but if the evolutionist is dumb before that mystery his antagonist is dumb too, and deludes himself with a mere play of words in lieu of an explanation.

Again, it is argued that the mode in which variations

Digitized by Google

arise—their apparently lawless and arbitrary character—is fatal to any orderly and satisfactory doctrine of evolution. Nature seizes on beneficial variations and perpetuates them, while she suppresses those variations that are harmful; but whence arise the variations? This objection does not strike us as very formidable. Granted that we cannot satisfactorily account for individual variations, it seems by no means impossible to conceive a satisfactory theory of the general method of variation. Atavism probably accounts for a great deal. We must take a comprehensive view of the evolutionary series, remembering that qualities, physical or mental, may remain latent for one or more generations, reappearing later in the stream of descent, and that therefore we have no right to be surprised at some characteristic arising that is not obviously derivable from the immediate ancestors. What is apparently inexplicable might be capable of an easy and obvious explanation if we could take a sufficiently comprehensive view of the facts. How naturally and easily some of the most mysterious phenomena of variation—such as reversion—fall into the ordered scheme of evolution when once we have got the proper clue. Thus it happens that facts, apparently most difficult of reconciliation with evolution, become, with fuller knowledge, the strongest proofs of the general accuracy of the theory. We need not dwell on the objection that there is no positive proof of the actual transition of one species into another. It may be fairly held that such proof is, *ex hypothesi*, impossible. The immense time probably required to effect specific changes and the almost inconceivable complexity of the phenomena render any precise demonstration impossible. All that the evolutionist may be fairly expected to show is that there are facts and analogies to prove that such a transition is possible, that it would account for a multitude of facts at present inexplicable, and that the distribution of species on the globe has undergone wide changes within geological times. All this has, we think, been fully effected. Whatever changes may pass over the doctrine of evolution—and we are probably still far from finality—DARWIN'S epoch-making work has destroyed for all time the old ideas on the permanence of species. Let us glance at the last objection—viz., that evolution throws no light on the origin of mind. We grant this most fully; but again we must insist that no other doctrine is a whit better off, and that the origin of mind, like the origin of life or the origin of matter, remains an insoluble mystery. There seems in the minds of many thinkers an idea that evolution is bound to hold the development of the living from the not living and the conscious from the unconscious. This is a radical error. The evolutionist, as such, has no opinion as to what was the original something from which all things have been developed. His concern is strictly with processes rather than origins. He is quite free to believe in an Eternal Mind or an Eternal Matter, or in both; but such beliefs are quite outside the range of science. They belong to theology, with which we have here nothing to do.

Opponents of evolution may fairly be asked not to confine their attention to admitted difficulties or to mysteries which are just as mysterious to the non-evolutionist as to the evolutionist, but to consider calmly the flood of light which the evolutionary hypothesis has cast upon the whole field of biology, to have regard to the immense mass of fact of which evolution affords at least a tenable and conceivable explanation, to consider the indirect evidence in its favour afforded by such phenomena as those of embryology, and to say whether it is not beyond comparison the most far-reaching and fruitful hypothesis ever conceived by science.

Two recent cases have directed popular attention to one of the most mysterious results of altered cerebral function—an absolute loss of that which is called "memory." The symptom is so striking, so conspicuous, and so simple, that it is natural for it to attract attention, and natural, also, that it should seem to be, in some way, susceptible of explanation. But, in truth, it is one of the derangements which bring into prominence the cerebral function of which we know perhaps less than we do of any other. There are two elements of the process which is included in the term "memory." They are generally confused, although one is often distinguished as "recollection." That which we call "recollection" is the voluntary use of memory; and it is the power of the will over memory, and not memory itself, which is lost in such cases as those which have recently attracted attention, and of which instances are familiar enough in medical science.

The physical basis of memory rests on the fact that every functional state of the brain leaves behind it a residual condition, in consequence of which that precise condition, in the same degree and the same combination, is more readily reproduced. The tendency for the state to occur again is the greater the more frequently it has previously occurred. It is this law which of course underlies all physical education, as well as all memory, commonly so termed. The occurrence of special nerve processes in association with each other leaves behind a tendency for the recurrence of the association, so that one "idea" causes the revival of another. The physiologist and the physician are mainly concerned only with the physical processes in the brain which correspond to and accompany the mental processes, with which they, as physicians or "physical physiologists" have less to do. But with these is combined the influence of revival of past activity, which is itself subject to the determining power which we call the "will." This association has baffled, and must apparently for ever baffle, our scrutiny. It is far beyond the range through which science can penetrate. We know of its workings by subjective facts on the one hand, and on the other by its effects. Among these effects is the susceptibility of the renewal of past brain processes to the will. We can voluntarily recall the impressions of the past, we can induce the same combinations of nerve action, but how we know not. True failure of "memory" can only be assumed in the cases in which there is a general depreciation of the cerebral functions. In consequence of impaired nutrition of the brain, the functional states do not leave the due residual effect which facilitates their revival. The change may be compared to the difference in the depth and in the permanence of the furrow in soils of different cohesion when the ploughshare cuts into them. On sand, for instance, as a much-quoted phrase reminds us, the ploughshare, instead of leaving a permanent furrow along which it can, if necessary, easily

Digitized by Google

glide again, makes only a slight depression, almost at once filled up by the non-coherent particles from the crests. Such failure of memory is seen in old age, in general degenerations of the brain tissue, and also, in a striking way, in some cases of cerebral anæmia. In profound deficiency of the blood, qualitative or quantitative, the state of the brain may be such that no mental impression leaves an enduring trace such as can permit its reproduction. In such conditions there is a true failure of memory. But we cannot assume that this is the case when there is only a simple loss of the power to revive past impressions by the will, such as occurs as the result of sudden local disease, or sudden injury. A severe concussion may be followed by a period during which there is unconscioness, and afterwards by a return of an apparently normal mental state. Everything up to the moment of the accident may be recollected, but everything afterwards may be an absolute blank. Even if the sufferer soon regains consciousness and appears to be in normal mental vigour, the residual states left by his mental processes are not within the power of will to recall. Such sudden change, probably in some cases at least a sudden local lesion, limits the power of the will in a curious way. The will can induce the revival only of those processes which occurred a long time previous to the alteration. It is a well-known fact that the earlier in life cerebral processes occur the more easily are they revived. After middle life the difference in the intensity of the residual states, or perhaps some difference in their relation to the mysterious influence of the will, makes them so much less amenable that such a sudden alteration, as may be caused by a local lesion, will withdraw them from the influence of volition. This can scarcely be spoken of as true loss of memory: it is loss of voluntary recollection, and that is all we can say.

Strange, indeed, is the apparent slightness of the cerebral influence which like a gearing apparatus keeps within the power of the will these residual states. Who does not know how a vivid dream may be recalled by some chance incident, revealing that an apparently dreamless night was filled with activity. In the curious brain state which follows a slight epileptic fit, in the state of "automatism," as it is termed, residual states must be produced as definite and as deep as any which occur in normal conditions, but they are beyond the power of the will and of any association to reproduce them. In a case recorded by Dr. GOWERS a carman drove his van across London, steering his way with precision through the crowded streets, and then suddenly found himself six miles distant from his destination. During the hour which had elapsed innumerable incidents must have left impressions deep enough to have enabled them to be reproduced at once by a voluntary effort, were it not for the sudden breaks in the continuity of consciousness which occurred—first, when he, as the saying is, "lost himself," and secondly, when he "came to himself." Rarely, in some like state at a subsequent period, the connexion with the past may be re-established. As a rule, in this morbid state, the missing link in the mechanism of voluntary recollection is never re-established. But it is otherwise when there is a sudden loss of the power of the will over the residual states produced under normal conditions, but which have been separated from volition by some sudden change. In such cases as those which have been discussed so much of late in the daily press, the residual states are there, and, at some link in the chain of association which exists between them, a renewal of the lost influence may occur, and may then quickly spread through the whole series; the memory may suddenly give signs, quickly increasing, of returning susceptibility to the will, which we call the power of recollection—a word which seems so simple, and yet denotes the greatest mystery of brain and mind.

Annotations.

"Ne quid nimis."

THE EAST LONDON WATER INQUIRY.

THE proceedings of this inquiry terminated last Saturday, when Mr. Pember, Q.C., addressed the Commissioners on behalf of the water company, and Mr. Balfour Browne, Q.C., replied on behalf of the East-end vestries. On the whole, the evidence contains but few facts that were not previously known or had not been published in the daily press. The position is much the same as it was. Briefly summarised it is as follows. Consequently on a severe and unusually prolonged drought the East London Water Company's storage reservoirs were reduced to such a serious extent that the company was compelled to limit the output of water. Had they not done so it is probable that the reservoirs would have run quite dry, and they were abstracting as much as could be taken from the River Lea without seriously affecting navigation. The result of this intermittent supply was to deprive all those consumers who were not provided with cisterns or other means of storage of a supply of water for the greater part of the day. It was stated that little or no inconvenience was experienced by those consumers who had cisterns in their houses, and that a 50-gallon cistern would have filled at the worst time of the drought in a quarter of an hour. The situation is much simplified by the admission of the company's own officials of two things—firstly, scarcity of water through an unusually dry season (which they, however, claim would not have happened if the London County Council had not blocked their proposals to extend their storage capacity some years ago); and, secondly, that if cisterns had not been abolished there would have been little inconvenience from the constant supply being made intermittent. In short, the causes which were responsible for the scarcity of water, both at the source of supply and at the house of the consumer, were one and the same—inadequate means of storage. The shortness of supply being due to the mains having been made defective by frost, as alleged by the County Council's engineer, seems improbable. One of two courses, it seems to us, therefore, is open to London if her inhabitants are to possess an adequate supply of water in the future under any abnormal circumstances whatever. That the present arrangements are not adequate under a stress of conditions has been demonstrated pretty clearly, but this could be remedied by increased provision for storage in the case of present resources and the existing system of supply. The alternate course is to draw water from other sources, which, as in the case of Wales, could be relied upon to serve a supply at all times without stint and certainly without the possibility of taint. The adoption of the former course, however, at its best can only be considered as so much temporary patchwork of a serious defect, while the latter would undoubtedly solve

Digitized by Google

the difficulty most satisfactorily if we exclude the question of the enormous cost which it must needs involve. We can easily imagine that this will be the substance of the report of the Commissioners of the recent inquiry, who, however, have not yet finished their task, inasmuch as they are making arrangements to visit the company's works and to inspect the private fittings in the consumers' houses during the present week. Their report will be awaited with unusual interest.

THE BRITISH MEDICAL ASSOCIATION AND THE MEDICAL SERVICES IN INDIA.

WE have received a number of communications from medical officers and members of the medical profession practising in India, as well as cuttings from various journals published in that country, regarding the action taken in the Public Health Section of the British Medical Association at their late meeting in respect more especially of the Indian Medical Service and the alleged utter inadequacy of the present sanitary administration of the Government of India. These communications emanate from officers and others of different ranks in various parts of India, and also in this country, and are of various lengths; but they all agree in protesting, more or less strongly and indignantly, against the statements which have been put forward, and in alleging that the picture which has been drawn, instead of being an accurate representation of the facts, is rather a caricature, unjust alike to the Indian Government and its medical services and to the profession generally in India. We have deemed it best, on the whole, and after careful consideration, not to publish the letters addressed to us. In the first place THE LANCET is in no way responsible for the repudiated statements; and in the second place we have made it a general rule not to publish contributions attacking other journals or affecting individuals connected with them for various reasons, the principal one being that their publication in THE LANCET might give rise to misconstruction and be attributed perhaps to an antagonistic spirit or to some unworthy motive or other. Moreover, on the present occasion the length of some of the communications, and the references to statements that have appeared elsewhere, introduce difficulties of a prohibitive kind. We have been led to make the foregoing remarks by way of apology for what might otherwise seem an apparent want of courtesy to various contributors for whom we entertain the highest respect. If we may be allowed to offer a suggestion as to the proper course to be adopted, it would be that our correspondents should address their communications or representations on the subject to the President of the British Medical Association.

THE DANGERS OF CYCLING.

THERE can be no manner of doubt that cycle riding has become popular with all classes, and, practised with moderation and within certain limits, no form of exercise can be more helpful in promoting a healthy balance of mind and body. The passion for propelling the body on wheels dates from the second decade of the present century, when the beaux of the West-end developed a predilection for dangling their legs from the hobby-horse. In 1846 a machine was constructed on which the rider balanced himself with his feet removed from the ground, and the "bone-shaker," the "ordinary," and its modified form the "Kangaroo" followed. But from no point of view were any of these machines satisfactory. It was not until the year 1885 that a really satisfactory machine, constructed upon rational principles, was introduced, and became the model upon which the most popular machines have since been [illegible]. Many improvements have, however, been made upon the old model, and wheeling has become popular with both sexes, with old and young, with the rich and, we may even add, the poor. Another cause of its popularity is, perhaps, the patronage given to cycling by many of the Royal family. In the popularity of the exercise, however, there lies a danger, and many of the accidents that occur might easily be avoided if the exercise were not indulged in so recklessly. Within the last few days there has been a series of deaths consequent upon cycle riding. In one case a child aged eleven years fell from a machine which he had hired and which he was incompetent to ride; in another case a man who had passed middle age collided with a van and fell under the wheels of the vehicle; and a minister and a well-known entomologist in America lost their lives from bicycle falls. With regard to children who hire bicycles the person who lets them out for hire should be held responsible if an accident occurs. We have often wondered that accidents from this cause do not happen more frequently. In poor neighbourhoods, especially on Saturday afternoons and Sunday mornings, lads of quite a tender age can be seen executing the most intricate and complicated patterns in the streets and roads, showing their utter inability to manage their machines. In the case of those of maturer years the responsibility rests with themselves, and those who have passed the prime of life should avoid as far as possible any endeavour to thread the intricate maze of vehicles in the main streets of our large cities; for, apart from the danger of loss of presence of mind, or of "side slip" when riding a "pneumatic" on slippery roads—a prolific source of accidents—the nervous strain which is set up is not at all conducive to health.

SMOKING IN COAL MINES.

THE evil wrought by want of thought, though not less injurious, may sometimes be more excusable than that which is done of set purpose. Not always, however, for there are instances in which the very omission implies a defect of will which is in a manner wilful. Among these may be reckoned such an example of heedless perversity as that which cost the lives of thirteen colliers last April in the Quarter Colliery, Stirlingshire. The cause of this catastrophe, as explained in the Board of Trade report, was the careless rather than thoughtless habit still prevalent among miners of smoking while underground. There could not have been here a question of ignorance. Working miners in our day are fully conscious of the grave risk incurred—nay, invited—by this mischievous custom. It is certainly no apology to plead the force of temptation. Men in other callings are constantly compelled by reasons of policy, which are far less cogent than the known claim of duty in respect of a neighbour's life, to smoke at set times and places, and at no other. It implies no hardship that the pit-worker should be made to do likewise. Neither does the alleged greater safety of Scotch mines, inasmuch as they are less liable to the explosion of firedamp, constitute a valid excuse. Gas, as is now well known, is not the only explosive medium. The mixture of air and finely divided coal dust suspended in it, which exists in every mine, provides in full measure the factors necessary to the production of this dangerous atmosphere. The best subterranean ventilation, the greatest skill in lamp construction, will do little to secure the workman's safety unless he be himself sufficiently alive to his own and his neighbour's danger to subordinate a desire the indulgence of which is criminal to the clearly recognised claims of mutual duty. Smoking underground is no more permissible than smoking near a powder magazine or a store of dynamite. The offence is in every case identical. Prevention, it is evident, is the sole remedy for its ruinous consequences, and this fact ought to be kept in view throughout the whole course of the miner's education and employment.

Digitized by Google

Even boyhood and school time are not too early to sow the seeds of precaution. Unions and like agencies at a later stage must use their influence to the same purpose and must at every possible occasion insist on the duty of abstinence from smoking, and, if needful, institute penalties. A daily search at the pit-mouth, and the temporary suspension of delinquents if detected smuggling matches or smoking materials, would be entirely reasonable deterrent measures. It must be evident that the danger to be met in this case is vital. Its prevention is of much deeper interest to the men than to any master, and any concession to personal liberty or option in regard to such a matter would be as idle as pernicious.

THE BATTLE OF THE CLUBS AT PORTSMOUTH.

IN an article by our special commissioner, published on Sept. 21st, mention was made of a branch of the Oddfellows Society which was proposing to admit to insurance benefits children of both sexes from the age of three months. We have received information that the proposition has been carried, and that the remuneration proposed is 2*s.* 6*d.* per annum for infants from three months to three years, and 2*s.* from three years to eighteen years in the case of boys, and to fifteen years in the case of girls. The medical officer attached to this body has accordingly resigned, owing to the increase of work without adequate remuneration which these conditions would impose upon him. Now, every member of the profession practising in the borough of Portsmouth has signed a pledge that he will not take any appointment to a friendly society vacated by reason of an increase of duties placed upon the medical officer. So it is evident that the offending society will get no local man to take the post, and we would earnestly adjure any member of the profession throughout the country who might be tempted to apply for the vacant post through seeing it advertised not to do so. The cry for "a living wage" and "a fair day's wage for a fair day's work" is all very well; but if it is to be carried out it must apply to all workers without exception. We should like to see any builder or plumber undertake to keep an ordinary house in repair for 2*s.* 6*d.* a year, finding his own tools and materials; and a baby is even more likely to go wrong than a modern house.

THE DAIRY SHOW.

AMONG the many exhibitions and shows which take place at the Royal Agricultural Hall, Islington, the Dairy Show, held under the auspices of the British Dairy Farmers' Association, of which the Prince of Wales is patron and the Earl of Derby president, is one of the most useful. Economical methods of preparing dairy produce are eminently desirable, both from the point of view of the consumer and the producer, and the ever-increasing number of exhibits at this Show is evidence that energy in this direction is not wanting. The exhibition of table poultry, showing the most improved methods of trussing, boning, and scraping for the market, gives evidence of attention to cleanliness as well as expedition, and the improvements in butter making are interesting to everyone. Among the new inventions exhibited is the Thistle Mechanical Milking Machine, by which a number of cows can be milked simultaneously. The apparatus consists of a rubber cup applied to each teat, from which the milk is drawn by a pump having an intermittent action imitating as far as possible that of a calf's mouth. The Radiator Butter-Maker, a combined skimmer and churn for producing Pasteurised butter automatically direct from the milk, is another novelty which will attract some attention, as will also the calf-rearing appliance and the various separators, coolers, &c., used in the economy of the dairy. Quite a new feature in the Show is the introduction of plans and models of dairies. The proper construction of buildings in which articles of food are prepared is as important as the quality of the articles themselves, and ventilation, drainage, and cleanliness are points which have too long been neglected. Some very good plans and models are shown, but there is considerable room for improvement; and it is to be hoped that the valuable prizes offered on this occasion by Sir James Blyth will stimulate designers to further endeavours in the sanitary construction of dairies. The Dairy Show, which closes to-day (Friday), is perhaps one of the most successful that has been held since the inception of these exhibitions nineteen years ago.

INTEMPERATE TEMPERANCE.

MR. JOSEPH MALINS of Birmingham has done his best to give an air of fanaticism to the recent National Temperance Congress at Chester. The Mayor of Chester had invited upwards of a thousand people to an "At home" to meet the Bishop of London and Sir Benjamin Ward Richardson. Not one-half of the guests were teetotalers. But the Mayor of Chester so far regarded the feelings of his principal guests as to supply abundance of non-alcoholic drinks. The only alcohol given was in the form of claret cup. But this was too much for Mr. Malins, and he condemned it at a public meeting, saying he hoped it would be the last time such an error of judgment should occur. Mr. Malins evidently thinks it his duty to judge the world, and feels himself quite equal to the function. A wiser and more gracious man would have thanked the Mayor for meeting them half-way and wished him God-speed the other half. This intemperance of teetotalers is hindering the temperance of the nation.

"VICARIOUS PHILANTHROPY."

SIR HENRY H. HOWORTH'S letters to the daily press are often interesting, though rarely dealing with questions of a medical character. But in his letter on the above subject he permits himself a reference to what he calls the "failure" of the movement for a memorial to Sir Andrew Clark, and especially to a letter from Mr. Gladstone to the *Weekly Sun* recommending an application to every medical man in Great Britain for a small subscription. Sir Henry Howorth protests against the incessant appeal for subscriptions to reward or glorify obscure people. He admits that Sir Andrew Clark was not an obscure person, but "he was certainly not a dramatic personage nor a particularly notable figure in the history of medicine." "To appeal to poverty-stricken medical men for a memorial to a successful physician, who left a great fortune and lived on velvet, is an example," says Sir Henry Howorth, "of the pernicious habit I am referring to." This is not a fair description of Sir Andrew Clark. He did not "live on velvet," whatever that may mean, and he was one of the hardest-working, most public-spirited, and effective physicians of recent years, in spite of the fact that he did not add so strikingly as some physicians to our knowledge, either of pathology or therapeutics. There is some reason in Sir Henry Howorth's protest, and even in its application to the methods advocated for the promotion of the memorial to Sir Andrew Clark. Mr. Gladstone's address at the beginning of the movement was one of the most gracious tributes to the profession, as well as to one of its leading members, which has ever been uttered, and the profession will not cease to be grateful to Mr. Gladstone, who spoke when he was not well enough to stand. But we agree with Sir Henry Howorth that the personal application to each member of the profession would be a mistake. The very beauty of such memorials is that they be unforced and spontaneous. We deny, however, that the memorial has been a failure. Mr. Gladstone's speech remains, and a sum of over £3000 has been raised from cheerful

Digitized by Google

givers. The mistake was in linking such an object to ordinary and prosaic purposes, and in associating too extensively with one institution, however deserving, a movement which should have been broad in its basis and in its application as Sir Andrew Clark himself was broad. It is perhaps now too late to give breadth to the movement. But we deny that it has been a failure. In this age of incessant and multifarious demands £3000 is not a mean sum to raise for such a purpose.

SYPHILITIC HÆMATOMA.

IN the *Deutsche Medicinische Wochenschrift* Dr. Hahn has published the particulars of a case of this rare affection of the dura mater. The patient was a man aged thirty-six, who had had syphilis about ten years before the onset of his nervous symptoms. These began with attacks of giddiness and severe headache, while his character underwent a great change. He finally had an attack of giddiness with loss of consciousness, and on the following day it was noticed that there was slight left ptosis, deviation of the tongue to the left on protrusion, deficient movements of the palate, indistinct articulation, and exaggerated reflexes. A few days later the following symptoms were also observed—viz., weakness of the right hand, diminution in the reflexes (especially of the knee-jerk on the right side), slight sensory disturbance, and impairment of hearing. He died about two weeks later comatose, having had previously some irregularity of breathing. At the necropsy it was found that over the whole of the left hemisphere, between the dura mater and pia mater, there was a thick layer of blood-clot; while on the right the dura mater was smooth, the pia mater being thickened and the convolutions flattened. At the base the pia mater was thickened, as well as in the Sylvian fissure, while the basilar and the carotid arteries were atheromatous. The left third nerve was flattened and apparently destroyed.

"THE GRIMSBY CHOLERA SCARE"—SO CALLED.

THE town council of Grimsby have decided, notwithstanding numerous protests to the contrary, to appoint a committee "to ascertain, if possible, who was responsible for the publication of the recent unfortunate scare in Grimsby"; and it is clear that the resolution is largely aimed at the medical profession and the press. The action is particularly ill-advised, for no one who knows the details of the Grimsby cholera outbreak in 1893 can do otherwise than feel that, had the town council been more open in admitting the existence of a disease which they could not distinguish from cholera, and which so alarmed those who knew the secret that they had the dead buried in lime, it would have been much better for Grimsby and for the country as a whole. When, after the visit of one of the inspectors of the Local Government Board, cholera was announced, it was too late to stamp it out. Then, as regards this year's experience, it is possibly permissible to say that there has been no cholera in Grimsby; but it is equally certain that clinically it was as impossible to distinguish the cases from cholera as it was during the early stages of true cholera in 1893. And, in view of the cesspits along the lines of the drains, by which soakage of filth into the soil in 1893 was not only favoured but practically ensured, there were many who quite anticipated a recurrence of cholera in that town. Were it not for the fact that much reliance is now being placed on the bacteriological test, no one would have doubted that there was a recrudescence of cholera in Grimsby on a small scale this year; and even some who esteem the bacteriological test most highly would by no means set aside the clinical history and the general antecedents merely [illegible] the disease Koch's comma bacillus did not happen to be found. We cannot but think that Grimsby got off very easily, by reason of the judgment as to the nature of their cases being determined almost solely, if not quite so, on the bacteriological basis. One thing, however, is certain—namely, that in view of the past history of Grimsby, and the chances of a recrudescence during the late exceptional season, the medical profession and the medical officer of health would have been very remiss if they had ignored the clinical indications of the fatal choleraic disease with which Grimsby was visited. And the town council would probably have been the first to blame them if, by chance, the bacteriological report had turned out otherwise or if the disease had continued to spread. One member of the town council urged that the rumour of last autumn had a commercial aspect. We cannot help thinking that the commercial aspect has had much more to do with the attempt to keep things quiet than it has with notifications and reports to the central government. There was everything this year to justify the notification of cases of cholera, and the occurrence of the rapidly fatal attacks in adults which took place in Grimsby amounted to "an outbreak of a dangerous disorder," such as every medical officer of health is bound to report to the Local Government Board.

"THE OLD MISSIONARY."

WE need make no apology for calling our readers' attention to a charming little work with the above title by Sir William W. Hunter. The old missionary was a medical missionary as well as a very wise and benevolent gentleman of large views and simple tastes, the pathos and unostentatious heroism of whose life consisted, to our minds, in its fruitless toil to attain the objects he had at heart, and in the sense of solitariness which falls to the lot of so many earnest and unassuming men of elevated character. There are many other interesting persons besides the old missionary in the book, and these, as well as the scenes of their labours, must have had some basis of real existence in the experience of their delineator. Those who know India and Indian life, its sorrows and joys, will have their associations touched and their memories awakened by the author's truthful description of scenes and his tender references to the little incidents of European life in India—mostly sad, but with a charm of their own withal, which none of us can, and most of us would not care to, obliterate altogether even if we could.

SANITARY EDUCATION.

IT is a healthy sign that workmen whose business it is to construct our dwellings are themselves beginning to see that it is not only to the advantage of the public in general that the work should be done in a way which sanitary science directs, but that it is to their own advantage that a stop should be put to all those practices which may be summed up in the phrase "jerry built." Among the first to have seen this is the master plumber, who, however willing he may be to do his work in a manner satisfactory to himself and to the public, is often handicapped by the fact that materials bought in the cheapest market are frequently supplied to him by the builder or the architect; and, however skilful the workman may be, the nature of the materials supplied preclude him from doing good work. It is he, however, who generally gets the blame if anything goes wrong; and we are glad to note that the National Association of Master Plumbers, which is making great progress throughout the country, has just formed a metropolitan branch of this association. Among the objects of the association are the raising of the status of the plumbing trade in the country, the prevention of contract work being done at unremunerative prices, and the confining [illegible]

Digitized by Google

work to plumbers. This last object is a very desirable one, for year by year our knowledge of sanitary principles is widened and the difficulty of the workman to keep pace with it increased. In London not a little has been done by the Sanitary Institute in this connexion, and the sanitary lectures delivered in various parts of the country are generally well appreciated by those whom they are intended to benefit. At Birmingham at the present time Dr. Bostock Hill is delivering a series of lectures on sanitary science at the Birmingham Municipal Technical School designed to impart a practical knowledge of the scientific principles of hygiene to sanitary engineers, builders, plumbers, and others engaged in house construction. Then again, besides the technical lectures for craftsmen, the numerous polytechnic and other institutes give courses of lectures on health science of a more popular character. These, however, which do not receive the attention they deserve, form an important factor in familiarising the general public with the principles of hygiene; and it is the education of the general public in these matters which, after all, must have the greatest influence in bringing about that hygienic millennium which is the ideal of every sanitarian.

RETIRED ARMY MEDICAL OFFICERS.

DEATH has been busy of late in the retired ranks of the Army Medical Department. Surgeon-General J. Irvine, Honorary Physician to the Queen, an officer who had seen much service during the Indian Mutiny, passed away on the 21st ult. at his residence at South Kensington, at the age of sixty-seven, just before the occasion of the commemoration of the thirty-eighth anniversary of the relief of Lucknow, in which he took part. Surgeon-General H. H. Massy, C.B., who died at Bournemouth on the 27th ult., at the age of seventy-five, had served in the Sutlej campaign, in the Crimean war, at the battles of the Alma, Balaclava, Inkerman, and Tchernaya, and other actions, and subsequently in the Indian Mutiny; and last in the list, but by no means least, Surgeon-General Sir Thomas Longmore, C.B., an obituary notice of whom will be found on another page, died on the 1st inst. at the age of seventy-nine. He served throughout the Crimean campaign, from its commencement until the termination of the siege of Sebastopol, without being absent from duty a single day, and subsequently in Bengal during the Mutiny. The services of these three medical officers make up altogether a very distinguished record.

THE "IONA" DISASTER.

BEFORE the sad impression created by the lamentable occurrence on board the steamer *Iona* altogether passes away, it may be well to make a few remarks on the subject and on the finding of the coroner's jury, which, we may add, does not strike us as by any means exemplifying the wisdom of the wise. We must say, in justice to the captain, that our study of the evidence leads us to infer that he acted promptly and judiciously and did his best under the unfortunate circumstances. As to the alleged anxiety which was said to have been evinced about the safety of the ship, the captain and crew of the *Iona* would simply have been culpably negligent if they had not at once concentrated their efforts in trying to secure this, for it meant the safety of everybody on board. The loss of life was bad enough as it was; but if the fire had spread, and it was rapidly spreading, the lives of all on board would most probably have been sacrificed. The great thing to be avoided, as everyone knows, on the occasion of a fire is panic, and the ringing of an alarm bell is, we should think, about the best possible way of creating it. It must be remembered, too, that a ship is, after all, a ship and not really a big floating hotel; but even were it a house on shore we should like to know whether a bedroom is usually provided with separate means of ingress and egress, as it was suggested should in future be the case with cabins in passenger ships. It seems that the passengers were warned in time for them to have escaped, but they were unfortunately not sufficiently impressed with the urgency of the danger and lost time in staying, poor creatures, to dress themselves. Even the heroic stewardess, whose life was sacrificed, did not appear to have realised the pressing urgency that existed. The jury were unanimously of opinion that the fire originated in the lamp-room, and they were probably right; but it was, after all, a matter of conjecture and opinion only. One of the main points connected with fires on shipboard that has to be guarded against is, as we have said, panic. The establishment of a system of "fire quarters" and periodical drill in connexion therewith will do much in this respect. A fire drill teaches all how to act, where to go, and what to do should the necessity really arise.

SCHOOL BOOKS AND INFECTIOUS DISEASE.

WE have from time to time referred to the risks that may be incurred by the reissue at a public library of books returned from infected houses, and it is certain that at the present time there are many medical officers of health who are taking steps towards the mitigation of these risks by notification to the librarian of the infected houses and by a disinfection of the infected books. Dr. Niven of Manchester, in his annual report for 1894, draws attention to the fact that in many schools the books used by the children are collected together into one room at the end of the day and redistributed indiscriminately on the following day without regard to the possible conveyance of infection by such means. It follows from this that a child with the initial symptoms of diphtheria or scarlet fever may have used a book on one day which on the day following may be used by a healthy child. This is certainly a risk which school managers will do well to consider, as also is the question of the separation of children's overclothing in the lobby. It would be well, too, in the same sense, to have regard to the redistribution of slates and pencils, and to the use of towels in the lavatories.

HYPNOTIC FRAUDS AND PUBLIC CREDULITY.

IT is characteristic of conspiracy that it tends to spontaneous disruption. Whether we deal with great or small combinations of this kind, with the quasi-sublime or with the ridiculous in imposture, the result is the same. A quarrel or a bribe may at any time introduce the thin end of the wedge, and the further work of cleavage is only a question of time. It is usually to the public advantage when offenders thus break with each other, and a degree of satisfaction on the part of outsiders is at such times only natural. Sometimes, however, this feeling is tempered by a touch of pity, as in a case recently examined in the Southport police-court. A youth eighteen years of age was charged with sleeping out of doors. He defended himself on the plea that his master, a professional hypnotist, had refused to pay him his wages. Some remarkable statements which followed throw a light on the kind of relations which exist between the hypnotist magician and his media. According to his own admissions the sufferings of this unfortunate "subject" were not imaginary. The art of the master juggler did not extend to the abolition of sensation. A pretended trance in which he lay for three days with his mouth stitched up was to the boy a period of wakeful and doubtless of painful sensibility, and we may safely conclude that certain injuries inflicted upon him at other times were likewise unrelieved by the anæsthesia of suggestion. The folly of

Digitized by Google

enduring—the morbid and culpable folly of encouraging—these miserable impostures ought to require no demonstration. Their exposure in this instance will, it is to be hoped, have some influence in weaning the minds of a credulous public from the attraction of a species of fraud to which it is far too ready to expose itself. We will not deny the strict justice of leaving the knave and his willing dupes in cases of this kind to live on one another and to find each other out. Still, this admission does not absolve us, as humane beings, of a certain social responsibility in the matter. Where the effect of the imposture implies no great personal detriment it may be allowed to work its own cure. Where, on the other hand, persons like the youth above mentioned are comparatively incapable of self-defence and are liable to somewhat serious injury, it will be generally admitted that some form of official supervision, and even at times of interference, is called for.

TYPHOID FEVER IN SUNDERLAND.

MR. T. W. THOMPSON, Inspector of the Local Government Board, has opened an inquiry into the sanitary condition of Sunderland, with especial reference to the fatal prevalence of typhoid fever. This is now on the decline, but the number of cases has been considerable. In the week ending Aug. 10th there were 14 cases; the 17th, 10; the 24th, 13; the 31st, 57; Sept. 7th, 104; the 14th, 105; the 21st, 95; the 28th, 70. The mortality of the town has placed it very unfavourably in the list of the large towns of England. The Mayor in his remarks on the occasion of Mr. Thompson's first visit seemed to find comfort in saying that the high death-rate of the borough was chiefly due to the great mortality from diarrhœa among children under three. But to the initiated this is as little creditable as the recurring epidemic of typhoid fever, and indeed has much the same significance. There is much difference of opinion as to the exact causes of the epidemic, the prevailing one attributing it to the ashpit system for the removal of refuse which is common. Mr. Thompson is making preparations for a very thorough investigation, the impartiality of which will go far to adjust the acute differences which divide the council on the subject, owners of property blaming parents and tenants for negligence and carelessness, others throwing the onus on the owners of property, which, it is contended, is fundamentally defective in a sanitary respect.

MORBID ANATOMY OF INFANTILE PARALYSIS.

IN the recently published number of *Brain* a full description is given by Dr. Trevelyan of the condition of the different structures of the spinal cord in a case of this disease, in which death occurred from independent causes eleven months after the onset of the paralysis. The patient was a girl six years of age who was suddenly seized with fever, nausea, and vomiting. Paralysis was observed on the second day and involved all four extremities. The sphincters were also affected at first. The arms began to recover three weeks after the onset of the attack, and the ultimate condition was one of almost complete paraplegia affecting the lower limbs, while the right arm also was weak. The knee-jerks were absent and there was a loss of faradaic reaction in the affected muscles, but little, if any, wasting. The condition of the spinal cord was especially observed. The ganglion cells were very much altered. The processes had disappeared and the cells themselves had become more or less formless masses. The nucleus and nucleolus seemed often to persist after the body of the cell had disappeared. Groups of minute but perfectly formed ganglion cells were seen here and there, chiefly in the parts corresponding to the lateral horns. The nerve fibrils were very much changed in the grey matter. Often they had entirely disappeared; where present they were mostly reduced to fine lines and they were frequently distinctly varicose. The fibres in the anterior roots as they passed through the white matter seemed to be fewer in number and thinner than normal. In only a few specimens did they seem to be degenerated. There were overgrowth and infiltration of the neuroglia, and in many parts of the grey matter of the cervical and lumbar enlargements translucent areas were visible, the result of destruction of nerve fibrils and ganglion cells, and with a high power enormous spider cells were visible in these translucent patches. The central canal was pervious throughout the cord. In many parts of the cord a greatly increased vascularity was evident, and advanced perivascular changes could be made out, often in the areas in which the central and peripheral vessels met. No distinct disease of the walls of vessels was made out. There was considerable cell infiltration in most parts of the cord. This was most distinct in the mid-cervical region. This cell infiltration was of two kinds, general and patchy, the patchy infiltration being frequently perivascular. The cells in this infiltration were also of two kinds, round and with processes; and there was a third kind of infiltration of large irregular cells without distinct processes in the area around the central canal and apparently derived from the cells lining the canal. The changes in the white matter were similar in kind but of much less intensity, and these changes extended throughout the whole length of the cord. From the study of this case—a case observed pathologically at an extremely interesting period, viz., after the intensely acute processes had subsided and before the cicatricial condition was established—Dr. Trevelyan is inclined to support the view identified chiefly with the names of Siemerling and Goldscheider, that this disease is of vascular and interstitial origin—i.e., that the changes in the ganglion cells are secondary to the changes in the vessels and interstitial tissue. As regards the ultimate origin of this disease, although no proof has yet been offered, there are strong reasons for supposing it to be infective.

THE HEALTH OF CORNWALL.

A CORRESPONDENT has lately directed attention to some very obvious sanitary defects in the north part of Cornwall. We have pleasure in acknowledging the publicity which has been given by our local contemporaries to his criticisms and sincerely wish that they may be the starting-point of more attention to questions of sanitation in this interesting county. The report of the Sanitary Committee of the County Council for August is before us and is not inconsistent in its general drift with the suggestions of our correspondent. The chairman, Mr. Silvanus Trevail, complains of delay on the part of the medical officers of health in sending in their reports, which may be taken as a sign that they are pressed by the duties of general practice, which, with their want of power and independence, makes them more indifferent in reporting what they see. There is a rise in the death-rate of August as compared with July; but as it is "only 13·49" the chairman thinks it very satisfactory and encouraging. It does not strike us as a very low death-rate for midsummer and a sparsely populated county. Some of the largest London parishes could boast as low a mortality. The zymotic death-rate has increased from 0·8 for July to 1·3 per 1000 for August, chiefly due to infantile diarrhœa. Diphtheria and croup have an increase from 10 cases and 1 death to 15 cases and 2 deaths. Scarlet fever has risen from 60 cases to 76, and shows an increase of 2 deaths. Typhoid fever has a decrease of 8 cases, but an increase of 3 deaths. Besides, we have no returns from several important districts, as Launceston (rural) St. Colomb, West Penwith, and Phillack, which have not even adopted the Notification Acts. Of thirty-six sanitary districts only two have isolation hospitals. The

Digitized by Google

chairman very properly points out the prevalence of scarlet fever at Camborne and Paul. At both places there was the same prevalence last year, and grave defects in the sanitary condition of each place were then pointed out. They remain absolutely the same, and the sanitary authorities seem in no way anxious "to make the necessary expenditure for the eradication of filth and disease." Cornwall is a county that, with a little intelligence on sanitary matters, would lend itself to ideal sanitary results. The farmer should be a perfect scavenger in his own interest. But landlords should be made to do their share of duty. The present sanitary condition seems to us "neither satisfactory nor encouraging."

ST. WINIFRIDE'S WELL.

FAITH-HEALING and miraculous cures are always interesting, and, whether supernatural or no, the fact of the cure remains. Our views on the subject were set forth recently in a leading article, but we are led to mention the subject again owing to our having received a paper by Dr. J. Johnston of Bolton. Dr. Johnston took a bicycle tour through North Wales and visited the famous holy well of St. Winifride. He tells us that numbers of crutches and the like, left by those who came halting and went away cured, are hung up in the chapel, and records of other cases are displayed on the walls. That such cures do take place is indisputable; as to the means there may be a difference of opinion. Our readers may remember some cases recorded by Professor George Buchanan of Glasgow,[1] when tumours spontaneously disappeared without any miraculous intervention, and though we should be the last to deny the powers of faith we can only assert that spontaneous "cure" of certain diseases is not unknown in the annals of science.

THE STRENGTHENING OF OUR DEFENCES.

EVERY week gives fresh *raison d'être* to our defence associations and makes us wish to see them in the strongest possible form for work and action, not only in a strictly defensive way, but in an aggressive spirit. The profession needs organisation for such purposes more than has yet been realised. The very best legal assistance should be within the means of such associations for the prosecution of certain cases before the law courts. The means of taking and procuring evidence for the presentation of cases before the General Medical Council is also an urgent desideratum. To these ends it seems to us that the first step is the consolidation of existing associations. The time for this seems to be ripe. There never was a period when so many medical men felt the necessity of membership of such societies. With such favouring circumstances and arguments the profession looks anxiously for the amalgamation of the Medical Defence Union and the London and Counties Medical Protection Society which, at present, greatly waste their resources and their strength in acting separately.

THE RETENTION OF DEAD BODIES IN HOUSES.

A propos of the late state of the weather a leading article in one of the daily papers refers to the retention of the dead in houses, and advocates removal to well-regulated mortuaries. The article is practically a review of another article in the *Free Review*, entitled "Living with the Dead." The assertion made by this latter writer, that it is usual to keep the dead a week or even five days, is, as our daily contemporary contends, an exaggeration, since in Liverpool most funerals take place not later than the fourth day, and many burials occur even sooner than this. Still, in such weather as we have had lately the retention of a body under certain circumstances for so short a period as twelve hours must be attended with much discomfort to the inhabitants of dwellings which contain no extra room for such a contingency. Not only is removal to a mortuary imperatively called for, but the speedy inclosure of the body in a coffin filled with coarsely powdered charcoal is greatly to be desired. As is well known, burial within twenty-four hours is absolutely enforced in many parts of the colonies and of the European continent. There are grave objections, sentimental and otherwise, to such a course being adopted in this country even in the hottest weather. But most medical men can remember cases where the inclosure of a body in the coffin has been rendered very desirable within a few hours after death, and where burial itself was equally demanded on the third or even the second day after death. It is much to be lamented that the study of disinfectants continues to be so neglected by undertakers and others with whom rests the care of the dead.

[1] THE LANCET, Nov. 7th, 1885.

MEDICAL REGISTRATION.

WE would remind our medical brethren of the imperative necessity both of promptly notifying any changes in their postal addresses to the branch registrar by whom they were originally registered, and also of answering at once any letter of inquiry that may be received from the registrar. Neglect of these precautions may result in the removal of names from the Register in consequence merely of the registered addresses being inaccurate. It should also be widely known that the General Medical Council may censure practitioners who employ unqualified assistants without exercising due personal supervision and control over them, and that several practitioners have been removed from the Register for permitting unqualified persons to practise under cover of their name and registered qualifications.

ARTIFICIAL DILATATION OF THE CERVIX IN PUERPERAL ECLAMPSIA.

THE October number of the *Revue Obstétricale Internationale* contains a report of an interesting case of puerperal eclampsia by Mdlle. de Moerloose of Brussels. The patient was a primipara, eight months' pregnant, who was admitted to hospital in a state of coma after having had six fits. There was marked general œdema, and the urine was highly albuminous. The os uteri admitted the tip of the finger, and there was no indication that labour was in progress. Chloral by the rectum, inhalations of chloroform, and morphine hypodermically were tried, but apparently without effect, as violent convulsions continued to occur at short intervals. Mdlle. de Moerloose therefore dilated the cervix with the fingers. Beginning with one finger, she was soon able to insert two fingers, and so on, till the os uteri was the size of a five-franc piece. The dilatation was done very gradually, the pressure with the fingers being made for a quarter of a hour, with intervals of the same time between each manipulation. No convulsions occurred while the dilatation was being effected. The membranes were then ruptured, and the head made to engage by pressure on the fundus. Delivery was completed with the forceps. The patient had two fits the same night, and two more on the day after delivery; she remained in a state of profound coma for several days, taking no nourishment except a little milk. The albuminuria did not commence to lessen till the eighth day. The patient was sufficiently well to leave the hospital on the fifteenth day. Mdlle. de Moerloose reports the case because she thinks that obstetricians are perhaps too much opposed to artificial dilatation of the cervix in similar cases. She does not mean that such a measure should be adopted as a matter of routine in each case, but considers that when drugs fail to produce an improvement in an hour, when the tissues are soft and dilatable, and the patient is evidently in a serious condition, digital dilatation

Digitized by Google

of the cervix in the manner above described offers the best chance of a favourable termination.

MEDICAL officers of both our own and of Continental armies will hear with great regret of the death, at an advanced age, of the eminent French surgeon, Baron Larrey, the son of the great military surgeon who accompanied the First Napoleon in all his brilliant campaigns and was present at his great battles. The late Baron Larrey had also seen a great deal of service in the field—from the siege of Antwerp in 1832 to the battle of Solferino—and was most deservedly popular and highly esteemed in and out of France for his great surgical talents and his eminent courtesy and kindness to all. Baron Larrey was a member of the French Institute and the Academy of Medicine. We hope in an early issue to publish a more extended notice of his work.

ON Tuesday, Oct. 22nd, the Royal Medical and Chirurgical Society will resume its meetings, and the first of the season promises a discussion of exceptional interest and value both to physicians and surgeons. Dr. Frederic Hewitt and Mr. Marmaduke Sheild have written a joint paper on Posture in its relation to Surgical Operations under Anæsthetics. This is one of those subjects which, as a rule, is only dealt with incidentally and in relation to particular cases, and it cannot fail to be of great service to operators to have the whole subject treated comprehensively and exhaustively. The paper will be illustrated by diagrams and drawings.

THE latest addition to the roll of gallant actions performed by medical men is that of Dr. Charles Toller of Ilfracombe, who, during the recent heavy gale which raged on our west coast and at the imminent risk of his life, descended by means of a rope a cliff on the Lee Bay Rocks, which are 150 feet in height, in order to apply restoratives to an apparently drowned person. Strenuous efforts were made by Dr. Toller to restore animation, and the patient partially rallied, but expired a few minutes before being landed at Ilfracombe in the lifeboat which had been sent to the rescue.

THE Lettsomian Lectures of the Medical Society of London will be delivered on Feb. 3rd and 17th and March 2nd, 1896, by W. Watson Cheyne, F.R.C.S., F.R.S., who has chosen for his subject, "The Objects and Limits of Operations for Cancer." The annual oration will be delivered on May 18th, 1895, by W. H. Allchin, M.D., F.R.C.P. The opening meeting of the society will be held on Monday next, when Sir James Crichton Browne, the President, will deliver his address.

THE sixty-fifth session of the Harveian Society of London will commence on Thursday, Oct. 17th, at 8.30 P.M., at the Stafford Rooms, Tichborne-street, Edgware-road, when Dr. Symes Thompson will read a paper on "The Climate of Egypt." All members of the profession are cordially invited to attend. The Harveian Lectures for 1895 will be delivered by Dr. M. Handfield-Jones in December.

THE annual grant amounting to £1700, of which King's College, London, was deprived by the late Government, is to be restored to the College next year by the present one, the restitution being accompanied by no stipulations as regards tests.

THE delivery of the Bradshaw Lecture at the Royal College of Physicians by Dr. Bradbury on some New Vasodilators, which was announced for Nov. 7th, has been postponed to Tuesday, Nov. 12th, at 5 P.M.

Pharmacology and Therapeutics.

BIBORATE OF SODA IN EPILEPSY.

SINCE Dr. Gowers first introduced this drug as a remedy in certain cases of epilepsy various observers have from time to time published observations on its effects. Amongst these are Stewart Lockie, Risien Russell, James Taylor, and Alexander in this country, Folsom and Jones in the United States, and Mairet, Féré, and others in France. The last-mentioned observer has recently published in the *Revue de Médecine* an account of an extensive series of observations of the effects of borax in epilepsy, the result of which is to show that, while in certain cases benefit is conferred by the use of the drug, in most cases the disadvantages are such as to more than counterbalance the slight benefits. Altogether 122 cases were treated, and of these 87 derived practically no benefit; but in some cases benefit was experienced. In 6 of these cases the benefit was doubtful on account of the short duration of the trial; in 7 patients amelioration was followed by relapse; and in 11 cases improvement resulted from the use of borax, but not so marked as the improvement following the use of bromides. The third chief group consisted of 11 cases in which undoubted, and in some cases remarkable, benefit resulted from the use of borax, all the more noteworthy because of the absence of benefit from bromide in large doses in some of those same cases. Full details of the treatment and its effect in these cases are given, and the tolerance of large doses of the drug in certain cases is striking. Dr. Féré next considers the various drawbacks to the treatment under the name of "borism." Intestinal troubles he found to be most troublesome—nausea, vomiting, and anorexia; but in certain cases the administration of borax in glycerine instead of in water obviated this drawback. Dryness of the skin and redness and inflammation of the mucous membranes were also produced. Dryness of the hair also followed, and in some cases loss of hair resulted, but only temporarily. The most frequent form of skin eruption was a kind of eczema answering to the description in most particulars of seborrhœic eczema; in other cases the eruption consisted of reddish patches which desquamated; while in still another class the eruption was papular and accompanied by prurigo of varying intensity. This also was sometimes followed by desquamation. In some cases a condition of great weakness succeeded prolonged treatment, this being the result, apparently, partly of the toxic effect of the drug and partly of the anorexia which followed its use. These different effects, it may be mentioned, have for the most part been mentioned by other observers, but another much more serious result is alluded to in this paper as following the use of borax in certain cases. This is an effect upon the kidneys, giving rise to the presence of albumin in the urine, and as a rule accompanied by œdema of the face and extremities, so that in all cases in which borax is given in anything like full doses it is essential that a careful watch should be kept upon the state of the urine. In one of the cases under Dr. Féré's observation uræmia and hyperpyrexia developed, and the patient died. The kidneys were found to be inflamed. The general facts in the paper indicate that, while borax is not as a rule to be compared to the bromides in regard to its efficacy in the treatment of epilepsy, still there are cases which, while intractable by the bromides, are very remarkably benefited by borax, but that the drug whenever it is given in large doses has certain disadvantages and even dangers which should be carefully guarded against.

THE USE OF COMPOUNDS OF BISMUTH AND NAPHTHOL AS INTESTINAL ANTISEPTICS.

Dr. Chaumier recommends these compounds as possessing to a large extent the antiseptic powers of β-naphthol, but not having the burning taste or other unpleasant properties of the latter. The naphtholate of bismuth is conveniently prescribed, and is in the form of a powder which is decomposed in the digestive tracts into naphthol and an oxide of bismuth. Dr. Chaumier has chiefly used these combinations in the diarrhœas of children and adults and also in diarrhœa due to tubercle and typhoid fever with successful results.

THE ACTION OF SALOPHENE IN CASES OF ACUTE ARTICULAR RHEUMATISM, CHOREA, AND NEURALGIA.

Dr. Augustin Huot of Paris has written a pamphlet on the action of this drug, which gives good results in the above

Digitized by Google

classes of disease without the drawbacks which often attend the use of salicylates. Chemically this drug is a salicylic ether of acetyl-paramido-phenol; it is insoluble in cold water and slightly soluble in hot, but is freely dissolved by alcohol and ether, and is easily decomposed in an alkaline medium. Salophene is not decomposed in the stomach, but is slowly decomposed by the intestinal secretions into its more elementary constituents, salicylic acid and acetyl-paramido-phenol; and the drug owes its antipyretic, analgesic, and antirheumatic properties to the salicylic acid chiefly, but also to the aniline bases, but without the toxic properties of the latter. Elimination takes place chiefly by the urine, and to some extent by the fæces. After quoting many cases in which the use of this drug produced beneficial effects, Dr. Huot concludes that salophene possesses the remedial properties of salicylate of soda and has not the inconveniences of the latter. It is well tolerated and does not irritate the stomach or the nervous system. It may be given in the powdered form, in cachets, or any other convenient manner, and an average dose would be from three to four grammes in twenty-four hours.

THE LIFE AND WORKS OF LOUIS PASTEUR, BY SIR JAMES PAGET.

UNDER the general heading "Scientific Worthies" and the sub-heading "Louis Pasteur" the following article originally appeared in *Nature* on March 26th, 1891. Having regard to the recent lamented death of M. Pasteur and to the fact that the particular number in question of *Nature* is now out of print, we have thought that it would be desirable and interesting to reproduce the article. Those members of our profession who have already read it will doubtless be glad of an opportunity of again perusing it, whilst those whose attention it has perhaps escaped will be glad to possess an estimate of the work of the great French chemist, who has now gone to his rest, from the pen of a great English surgeon who is happily still living. Although published in 1891 the article is practically up to date, for since that time no more research work has been undertaken by M. Pasteur himself. For permission to reprint the article we are indebted to its author, Sir James Paget, and to Messrs. Macmillan and Co., the proprietors of *Nature*.

Louis Pasteur was born on Dec. 27th, 1822, at Dôle, where his father, an old soldier who had been decorated on the field of battle, worked hard as a tanner. He was an earnest, industrious, and thoughtful man, fond of reading, and very desirous that his son should be well educated and should gain renown in some branch of learning. Father and mother, alike in their enthusiasm and ambition, devoted themselves to their son—they would "make a man of him," they said. In 1825 they removed to Arbois, and as soon as he was old enough to be admitted as a day-boy Pasteur began his studies in the Communal College, and there, after the first year or two, he worked hard and gained distinction. Thence he proceeded to Besançon, and thence, after a year's successful study, to the École Normale in Paris, to which, after gaining a high place in the entrance examination, he was admitted in 1843. His devotion to chemistry had begun while he was a pupil of Professor Darlay at Besançon, and now he studied it under Dumas at the Sorbonne and Balard at the École Normale. His love of science became intense: he spent every day in attendance on the lectures, in reading, and in practical work in both chemistry and physics.

Among the teachers in the École by whom he was most encouraged was M. Delafosse, who was especially studying molecular physics, and it was after a conversation with him that Pasteur was guided to the careful study of crystals and to the inquiry which led him to his first important discovery. It was known that the tartrate and the paratartrate of soda and ammonia, though exactly isomeric, similar in their atomic composition, specific gravity, and crystalline form, yet differed, not only in many of their chemical relations, but, as Biot had shown, in the fact that a watery solution of the tartrate deflected the plane of polarised light, and that of the paratartrate did not. Pasteur could not believe that bodies apparently identical in atomic composition and construction could thus differ in their relations to light. He had already observed a dissimilarity between the crystals of the tartaric and of the paratartaric acids, in that the latter were and the former were not symmetrical, and he found the same difference between the crystals of their salts. Now, by a laborious study and repeated measurements of the crystals of these and other similar compounds, he showed that in the paratartaric (now called racemic) acid there are two distinct forms of tartaric acid, of which the one (dextro-tartaric) is identical with the ordinary tartaric and, like it, in solution deflects light to the right, the other (lævo-tartaric) deflects it to the left. The two in combination, as they occur in the ordinary paratartaric acid, neutralise one another in their influences on polarised light and do not deflect it in either direction. Similarly, he next found that the crystals of the two acids and of their respective salts are different in their forms; those of the dextro-tartaric and its salts are similar to those of the ordinary tartaric and its salts in their dissymmetry; those of the lævo-tartaric are also dyssymmetrical, but in the opposite direction; those of the two combined in the paratartaric and its salts are symmetrical. Thus was explained the seeming anomaly of so distinct a difference between bodies exactly isomeric. A great problem was solved, and it was among its results that gradually the way was made clearer by which the synthesis of organic alkaloids and of sugars has been achieved.

These researches had occupied six years, and Pasteur had gained by them an early high renown, and he hoped that by continuing to work on the same lines he might obtain results yet more important, especially in the contrast of the symmetrical forms of crystals derived from the chemistry of dead substances and the dissymmetrical of those derived from the chemistry of living bodies. He had invented instruments and methods for experiments. But it chanced that at this period of his work he was, in 1854, appointed Dean of the Faculty of Sciences at Lille, and, though he gave up crystallography with great regret, he determined to investigate and teach a subject of more direct utility. The chief industry of the town was in the manufacture of alcohol from beetroot and corn, and he decided to teach the scientific methods of improving it, and to promote the scientific brewing of beer that might compete with those of Germany and Austria. Hence fermentation became his chief study, and in this was the beginning of the researches which led to the most important of his discoveries. But although it may have seemed like entering on a new subject, the change was an illustration of the regular sequence that may be observed in the order of all Pasteur's work, for among the facts which had most influence on the course of his investigations was one which he had observed in his study of the tartaric salts. He had traced the fermentation of the ordinary right tartrate of ammonia in a solution containing albuminous matter and had observed the coincident appearance of a distinct microorganism. Then he had shown the breaking up of the composition of the paratartaric acid by a similar process of fermentation by putting a minute portion of green mould into water containing phosphate of potassium and ammonia, but no albuminous matter. Here also there was an abundant formation of organisms, and with this the gradual disappearance of the dextro-tartaric acid, of which, as other experiments showed, the carbon was taken for the sustenance and growth of the organism of the mould. In both cases the fermentation had seemed due to the action of a living organism. Pasteur's belief that these and all processes of fermentation were primarily and essentially due to the presence and action of minute living organisms in the variously fermentescible fluids led him to study them with the combined chemical and microscopical research which no one before him had ever used with the same constancy or the same skill. It was, indeed, a combination of methods of research which had hardly ever before been used. There were excellent chemists and there were excellent microscopists, but they usually worked apart and hardly helped one another. Pasteur—well instructed in exact methods of research, and both chemist and microscopist—attained results far beyond what any before him had reached. It was no easy thing for him to justify the study of fermentation on the lines suggested by what was called the vitalistic or germ theory when the hypothesis of "spontaneous generation" was held by many, and when the whole process of fermentation seemed so well explained by the chemical theory of Berzelius or by that of communicated molecular motion held by Liebig and others who agreed with him in thinking that the organisms in fermenting liquids might be considered as

Digitized by Google

accidental, except in so far as they might supply organic matter to the liquid. But Pasteur did more than justify the germ theory, for he proved its truth by a multitude of facts previously unobserved and from which he constructed general principles of which both the scientific value and the practical utility are now beyond estimate.

It is not possible to describe in detail or in chronological order the course and methods of Pasteur's researches on the various fermentations and on processes closely allied to them. Only their chief results can here be told; only the things which he discovered or which, since he studied them, have been deemed not merely probable, but sure. Thus he proved the constant presence of living micro-organisms, not only in yeast, in which Cagniard-Latour, and Schwann especially, had studied them, but in all the fermenting substances that he examined; he proved the certain and complete prevention of fermentation, putrefaction, and other similar processes in many substances, however naturally subject to them, by the exclusion of all micro-organisms and their germs or by their destruction if present; and he proved the constant presence of various micro-organisms and their germs in the air and water, in the earth, in dust and dirt of every kind—their abundance "everywhere." By the proof of these things the evidence became complete that fermentations and similar processes are primarily and essentially due to the action of organisms living in the fermenting substance. But, more than this, it was ascertained that each method of fermentation—vinous, lactic, acetic, putrefactive, or whatever it may be—is due to a distinct specific micro-organism appropriate to that method, and by its own vital processes initiating the changes which lead to the formation of the "specific products" of the fermentation, the alcohol, the vinegar, the virus, or whatever else. For each specific micro-organism has to live on the constituents of an appropriate fermentescible fluid which it decomposes, assimilating to itself such elementary substances as it needs for its own maintenance and increase, and leaving the rest to combine in the forming of the "specific products." Further, and most importantly, it was made certain by Pasteur's investigations that, by various appropriate methods of "cultivation" which he invented, the individuals of each species of ferment may be separated from others with which they are mingled, and that, thus separated, the individuals of each species may by means of a "pure cultivation" be multiplied indefinitely, as, especially, in the production of "pure yeast." And in certain instances it was shown that the active power of micro-organisms may, by cultivation, be so "attenuated" that they will produce only comparatively slight changes in substances which, in their natural state, they potently affect.

The most direct applications of the results of Pasteur's studies of fermentation were, naturally, made in the manufacture of wine and vinegar, and, at a later time, of beer. The "diseases," as they were fairly called, of these fermented liquors, the "thickness," "ropiness," "sourness," and others, could be traced to the disturbing influences of various other micro-organisms mingled with those of pure yeast, the true alcoholic ferment, and each producing an injurious method of fermentation. This being made sure, the prevention of the diseases became possible by the exclusion or destruction of every organism other than than the true one; and of this one the proper cultivation could insure the sufficient production. The methods of thus preventing or arresting the diseases have become too various to be described here. Among them is that of heating wines and beers sufficiently to destroy all the germs remaining in them; and the uses of this, which has been specially called Pasteurisation, and of many others, have made brewing and wine-making nearly secure against the great losses to which, before Pasteur's time, they were always liable from the disturbances of their fermentations.

The utility of the proof that fermentations, including the putrefactive, are absolutely dependent on the action of living micro-organisms was speedily shown in the prevention or remedy of diseases far more important than those of wine and beer. The discovery of the causes and processes of what were justly called the "diseases" of fermented liquids enlarged the whole range of a great section of pathology, showing, as it soon did, so intimate relations between contagious diseases and disordered fermentations that it became safe to apply the facts found in the more simple to the study and treatment of the most complex. The study of the diseases of fermented liquids led straightway to the practice of antiseptic surgery. Its first practical application in medicine was in 1862, when Pasteur, who had proved the existence of a living organism in fermenting ammoniacal urine from a diseased bladder, recommended the washing of such bladders with a solution of boracic acid, now a well known "germicide." This was done successfully by M. Guyon, and the practice is still commonly followed.

For the treatment of wounds and of parts exposed by wounds, the whole subject of the complete exclusion of micro-organisms, and of their destruction if present, was, in and after 1865, studied with especial care by Sir Joseph Lister, and the results obtained by him and others following his example were so convincing that the antiseptic practice, which many justly call Listerism, is followed everywhere by every surgeon of repute. The methods of excluding micro-organisms from all wounds, the antiseptic substances employed, the modes of applying them are more than need be told, and they increase every year; but they have all the same design—the complete exclusion or destruction of all living germs and micro-organisms capable of exciting putrefaction or any other fermentation in parts exposed by wounds, their exclusion from air, water, sponges, surgical instruments, dressings, and everything that can come in contact with such parts. And the system is not nearly limited to the treatment of wounds. In various methods and degrees it is applied in the construction of hospitals and infirmaries, in the prevention of the spread of infection and of every form of blood-poisoning. In is impossible to estimate the number of the thousands of lives that are thus annually saved by practices which are the direct consequences of Pasteur's observations on the action of living ferments and of Lister's application of them. In the practice of surgery alone they are by far the most important of the means by which the risks of death or serious illness after wounds are reduced to less than half of what they were thirty years ago, and of the means by which a large number of operations, such as, at that time, would have been so dangerous that no prudent surgeon would have performed them, are now safely done.

In antiseptic practice and in the manufactures connected with fermentation, the design is to exclude or destroy all micro-organisms. Many kinds might be harmless, but at present there are no ready and sure means of excluding only those from which mischief might arise, and, therefore, in the schemes for complete exclusion, no account is taken of the great general principle established by Pasteur, that each method of fermentation is due to the action of one special living organism. This in relation to contagious diseases would now have become one of the chief subjects of his study. But again he was obliged to change the subject of his work, for in 1865 he was urged by Dumas, and was forced to consent, to undertake the investigation of a disease of silkworms in the south of France. Since 1849 this disease, called *pébrine*, had been ruinously prevalent. In 1865 the loss due to it was estimated at four millions sterling, and it had spread to many other countries from which silkworms' eggs had been brought to France. M. Quatrefages had reported to the Academy that, among the results of many previous inquiries, especially by Italian naturalists, minute "corpuscles" had been found in the bodies of diseased silkworms and in the moths and their eggs. Pasteur, of course, suspected that these were disease-giving organisms, and directed his chief studies to them, though not without making a careful investigation of the whole disease, a task in which he proved himself to be not only a chemist and a microscopist, but an excellent clinical observer. He soon found that among several diseases of silkworms the two most important were *pébrine*, which was specially called *the* silkworm disease and was the most destructive, and another, often very prevalent, called *flacherie*. He found "corpuscles" in both, and he confirmed and widely extended the observations of those who had already studied them. But the most important facts, both for the prevention of the *pébrine* and for general pathology, were those by which he showed that it was not only contagious but hereditary. The proof of its being contagious was chiefly seen, as by others, in the inoculations of silkworms through accidental wounds, and in the consequences of their feeding on mulberry-leaves on which the disease germs had been deposited. Many of the worms thus or in any other way infected soon died; in many the material for their silk was spoiled; in others the disease continued, after their spinning, in their chrysalides and in the moths developed from them. These moths laid diseased eggs, and of these were born diseased worms which died young or, at the most, were spoiled for the production of silk, and so long as they lived were sources of contagion. Thus the disease passed on by inheritance from year to year.

Digitized by Google

The germs in eggs laid by diseased moths survived, but those left on leaves, or in the dust, or in the bodies of dead moths, soon perished; only in the diseased and living eggs was the contagion maintained. These things were proved by repeated experiments and by observations by Pasteur in his own breeding-chamber, year after year, and they made him believe that the disease might be put an end to by the destruction of all diseased eggs. To this end he invented the plan which has been universally adopted, and has restored a source of wealth to the silk districts. Each female moth, when ready to lay eggs, is placed on a separate piece of linen on which it may lay them all. After it has laid them and has died it is dried and then pounded in water, and the water is examined microscopically. If "corpuscles" are found in it, the whole of the eggs of this moth, and the linen on which they were laid, are burnt; if no corpuscles are found, the eggs are kept, to be in due time hatched, and they yield healthy silkworms.

Pasteur continued these studies for four years, going every year for several months to a little house near Alais, in which he watched every step in the life of the silkworms bred and fed by himself and others. His other investigations had thus been in no small degree interrupted; but worse interruption came in October, 1868, when, as it seemed from overwork, he had a paralytic stroke. For a time his life was in great peril, but, happily, he recovered, and without mental impairment, though with permanent partial loss of power on his left side. For nearly two years he could do very little beyond directing experiments for repeating and testing his researches at Alais in 1869, and in Austria in 1870. Then came the French-German war, the misery of which, added to that of his paralysis, made him utterly unfit for work. At the end of the war he returned to work, and, after careful researches on the diseases of beer similar to those by which he had studied the diseases of wines, he gave himself especially to the study of the "virulent diseases" of animals—the diseases which might reasonably be suspected to be due to different kinds of "virus" derived from different species of micro-organisms. The suspicion was already justified by what he had observed in the diseases of wine and beer and by some more direct facts, for, in 1850, Rayer and Davaine had found organisms in the blood of animals with anthrax; and, in 1865, Davaine, stirred by Pasteur's recent demonstrations of organisms much like these as agents in the butyric fermentation, had gathered evidence of the absolute dependence of anthrax on the presence of these organisms in the blood. But his observations were disputed and his conclusions were not accepted till Pasteur proved that they were correct, and then extended his researches over a far wider range of subjects. The objects of research in this wider range included, indeed, only a small proportion of the diseases connected with micro-organisms, but in a few years it was made certain that some, and probable that all, of the diseases usually classed as virulent, contagious, or specific, are due to distinct living micro-organisms, and to the products of the changes which are initiated by them in the blood or other fluids or substances in which they live. Thus, that which had often been an ingenious hypothesis of a *contagium animatum* became an accepted general law; diseases that had been called virulent were now more often called parasitic; and it may justly be said that Pasteur's researches were the efficient beginning of the vast science of bacteriology—vast alike in natural history and in pathology and in its intimate relations with organic chemistry.

Besides ascertaining the micro-organisms appropriate to several diseases, Pasteur, still working on the lines which he had followed in his studies of fermentation and of the diseases of beer and wine, found various means of "cultivating" the germs, separating them, multiplying them, and then testing their different influences on different animals, or on the same animals in different conditions, or after various changes induced in themselves. Among these changes the most important and most fruitful in its further study were the various means of "attenuation" by which the virulence of disease-producing micro-organisms can gradually be so diminished that at last they can, without harm, be inoculated or injected into an animal which they would have rapidly killed if similarly inserted in their natural state. And some of these injections were shown to be better than harmless, for, by conveying the disease in a very mild form, they rendered the animal for some considerable time insusceptible of that same disease in a more severe form; they conferred an immunity similar to that given by mild attacks of the contagious fevers which, as it is commonly and often truly said, "can be had only once." Or, as Pasteur held, the inoculation with the attenuated virus was similar to vaccination, which gives protection from small-pox by producing similar disease in a milder form. Hence began the practice of "protective inoculation" for many diseases besides small-pox.

In studying the methods of attenuation Pasteur found many facts which are not only valuable in bacteriology, but are likely to help to the knowledge of important principles in general pathology. To cite only a few examples—he found marked differences among the micro-organisms of different ferments in their degrees of dependence on air. The great majority need oxygen for the maintenance of life, but unlike these, which he named aërobic, were some anaërobic, the first examples ever known of organisms capable of living without oxygen. He showed that the bacilli of anthrax, being aërobic, soon perish and disappear in the blood of the animals that have died of the diseases due to them, and that in the same blood the anaërobic septic bacilli needing no oxygen now appear and multiply. In anthrax, also, he showed that the attenuation may best be attained by keeping the cultivated bacilli at a high temperature (about 42° C.) for a certain number of days, regulated according to daily tests of the reduction of their virulence. In the end they become incapable of killing even mice, and are protective for sheep and cattle and other animals, which in their natural intensity they would rarely fail to kill. In chicken-cholera, the disease for which the first experiments in protective inoculation were made, he showed that the due attenuation can be obtained by a series of successive cultivations of the micro-organisms in pure air, provided that intervals of several days or weeks are allowed between each two of the cultivations in the series. In experiments on the transmission of the virus of a disease of one species through a succession of animals of another species he showed that the virulence of the bacilli of swine-erysipelas was increased by transmission through pigeons, but diminished by transmission through rabbits. And as to the varying susceptibility of the same animal under different conditions, a fact so commonly observed in man, he showed that chickens, which are ordinarily insusceptible of anthrax, could be made susceptible by lowering their temperature. They became again insusceptible when their natural temperature was restored, and when apparently dying of anthrax in the cold they recovered if warmed.

It was a step far beyond what had been obtained by protective inoculations when Pasteur invented and proved the utility of his treatment of rabies. Here he proved that when a virus has been inoculated or in any way so inserted that it may justly be deemed sure to destroy life, this result may, at least in the case of rabies, be prevented by a daily or otherwise gradual series of inoculations, beginning with the same virus very attenuated and diminishing the degree of attenuation till it is used in such intensity as, without the previous graduated inoculations, would certainly have been fatal. The results of the treatment of rabies on this principle are well known; its success is certain and is enough to justify the hope that by similar treatment, whether with virus simply attenuated or with some "lymph" derived from a cultivated virus or from the chemical products of its action on the liquids in which it has grown, other specific diseases may be similarly controlled. This is especially probable for those in which, as in rabies, there is a clear interval between the entrance of the virus and the first outbreak of the disease; and it is becoming very probable that tuberculosis will be one of these. But it would be useless to imagine the probabilities of what will now follow from the researches that have already followed the discoveries of Pasteur.

It hardly need be said that this summary of Pasteur's life and works, and of the chief results to which they have led, can give no fair estimate of the number and the variety of his experiments and observations. Only a complete personal study of his published works, and especially of those in the *Comptes Rendus de l'Académie des Sciences*, can give this. Yet even a mere summary may indicate the most notable points that may be studied in his scientific character. Of his charming personal character there is no need to speak here. Clearly, he had a native fitness and love for the study of natural science, and these were well educated and have been manifest in his whole life. But with this loving devotion to science he has shown not only a very rare power both of thinking and of observing, but that spirit of enterprise which stirs to constant activity in the search after truth, especially by way of experiment. With the power of accurately thinking what is likely to be true, he shows a happily adjusted ingenuity in the invention of experiments

Digitized by Google

for tests of thoughts, and the habit of doubting the value of any scientific thought, even of his own, which does not bear experimental tests. Especially, the thoughts of what may be true in biology seem to have been submitted, if possible, to tests as strict as those that may be used in chemistry and physics; and they appear to have been repeated and varied with admirable patience and perseverance whenever any doubt of previous conclusions was felt by himself or reasonably expressed by others. He has practised what he urged on his younger colleagues at the opening of the Pasteur Institute: "N'avancez rien qui ne puisse être prouvé d'une façon simple et décisive." Besides, with all his mental power and caution, we can see, in the course and results of Pasteur's work, the evidence of rare courage and strong will, and of singular skill in the use of the best means of scientific investigation. He has been chemist, microscopist, and naturalist, and has applied all the knowledge thus gained to the practical study of pathology. It is not strange that he has attained the results of which the best, and only the best, have here been told.

The honours that have been bestowed on Pasteur need not be mentioned. His chief reward may be in the happiness of seeing some of the results of his life-long work; and, indeed, very few scientific men have lived to see their work bear such good and abundant fruit. No field of biological study has in the last twenty years been so effectually studied as that which he opened, and in which he showed the right methods of research. Now, wherever biology is largely taught, the bacteriological laboratory has its place with the chemical and the physiological; and, for a memorial of the gratitude not only of France, but of many other nations, there is in Paris the Pasteur Institute, which was constructed at a cost of more than £100,000, and was opened in 1889. Here he may not only see the daily use of his treatment for the prevention of rabies, but may observe and still take his part in the extension of the vast range of knowledge in which there has been constant increase ever since the first sure steps were made by his discoveries.

Park-square-west, N.W. JAMES PAGET.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Glamorganshire County Sanitary District.—Dr. William Williams, the county medical officer of health, has recently made a valuable addition to the public health literature of his county in the shape of a little volume entitled "A Sanitary Survey of Glamorganshire." It formed the subject for Dr. Williams' thesis for the degree of Doctor of Medicine at Oxford University, and it is a contribution which should be of valuable assistance to the members of the Glamorganshire County Council, as also to those of the local authorities throughout the county. In the introduction of the volume there is a letter from Sir Henry Acland to Dr. Williams, which forms in itself a dissertation on public health questions. Sir Henry Acland refers to the wide range of knowledge which the medical officer of health of the present day is expected to possess; in reference to this point he observes: "Many live who can hardly believe that such modern officers are members of the same profession as some of the old but wise and kindly practitioners of fifty years ago." Dr. Williams' little volume contains a sanitary district diagram of the county to which it relates, a provision that certainly much facilitates the reading and understanding of a medical officer's report. In Part I. of the volume an account is given of the physical features of the county, of its industries, surface geology, and water-supply. Part II. treats of the health history and vital statistics of the county, and in this part there is an instructive *résumé* of all the inspections in various parts of the county which have been from time to time made by the inspectors of the Local Government Board. Part III. treats of the sanitary condition of the various districts in the administrative county; and it is here that Dr. Williams gives a complete account of each district, together with such recommendations and advice as the circumstances of each case render desirable. In Dr. Williams' annual report for 1894, which has also just reached us, the Sanitary Committee of the County Council is urged to be more energetic in the matter of such powers as have been conferred upon them by the Rivers' Pollution Prevention Acts and the Housing of the Working Classes Act. During 1894 the birth-rate of the rural districts of the county was higher than that of the urban, indicating, Dr. Williams observes, that some of the rural districts are so only in name. The general death-rate of the county was 16·9 per 1000, the rates varying from 8·6 to 22·1. The infantile mortality was a high one—168·1 per 1000 births compared with 155·1 in the preceding year. There were 1726 cases of scarlet fever notified during the year, but out of this number it is astonishing to learn that only 2 were removed to an isolation hospital. Dr. Williams observes that the working classes in the county act on the belief that, as children are bound sooner or later to contract scarlet fever, it is therefore their duty in the presence of a mild type of the disease to give their children an opportunity of contracting it; in fact, one of the local medical officers reports that in his district parents under this mistaken sense of duty have taken their children into infected houses. It would be well, if possible, for the district medical officers of health to impress upon the public the obvious advantages from the point of view of survival of postponing the attacks until a late age period. Five cases of typhus fever were reported from Merthyr; the first 2 were hop-pickers returned from Herefordshire, and the remaining 3 (the attendants) contracted the disease from them.

Reading Urban Sanitary District.—During 1894 the Reading Sanitary Committee requested from Mr. Alfred Ashby, the medical officer of health, a report upon the desirability or otherwise of adding phthisis to the list of notifiable diseases. Mr. Ashby points out in his report that to regard phthisis as infectious in the same sense as small-pox, scarlet fever, &c., is to overstate the case, and he calls attention to the enormous factor which the personal equation may be held to play in the question. In other words, he insists upon the importance of improving the environment of the individual by the admission of sunlight and fresh air. It would, he remarks, be quite out of the question to separate phthisical persons from their families and to confine them in isolation hospitals for months and even years. In short, he discountenances notification and advises the distribution of leaflets. In this direction he thinks that probably as much might be done without as with notification, since medical practitioners could distribute such leaflets to the patients under their care. The disinfection of rooms, &c., in which a death from phthisis has taken place is also advised. The important subject of providing a satisfactory isolation hospital at Reading still appears to be, if not in actual abeyance, in a state akin to it. The council, it would seem, appoint committees to consider the matter, but exhibit a tendency to reject their recommendations.

"SMALL-POX IN BRISTOL DURING THE YEAR 1893-94."

Under this title Dr. D. S. Davies, with the aid of Dr. Heaven and Dr. Dowson, assistant medical officers of health for the city, has issued a very instructive report. After referring to the history of small-pox in Bristol since the year 1856 and to the mortality which it occasioned, a short account is given of the tramp epidemic of 1893, and then follows a full consideration of the 1893-94 epidemic. To cope with the epidemic required all the resources at the command of the sanitary authority, and although no cases from Bristol were refused isolation owing to lack of accommodation it is frankly admitted that at a critical point of the epidemic there was but one vacant bed. The tables in the report relate to 360 cases which occurred during the 1893-94 outbreak. At all ages under ten years the protective value of vaccination was well exemplified, and at that age period there were among the vaccinated not only no deaths but no serious cases. Out of the 360 attacks, 36, or 10 per cent., proved fatal, and of these 6 were children, all unvaccinated, under ten years of age. The figures in the following age groups show, as usual, the gradually decreasing power of the primary vaccination as age advances, and the results both as regards severity and fatality are, speaking generally, in accordance with those again and again observed. In commenting upon the degree of protection afforded by vaccination, the authors of the report refer to and deplore the growing tendency among some medical practitioners to produce but one small scar—a practice which not only confers a false sense of security

Digitized by Google

upon the subject, but tends to the disrepute of vaccination. Dr. Davies and his colleagues record a fatal case of small-pox in a vaccinated child aged thirteen, the only death they have met with in a vaccinated person under fifteen years of age in the course of two epidemics comprising 687 cases, 96 of which were in children under fifteen. There is also recorded an interesting instance of a child born in the small-pox hospital during the early convalescence of the mother from a discrete attack; the child remained in hospital with the mother for twenty-one days, but was susceptible neither to small-pox nor to vaccination. Passing to a consideration of the behaviour of the vaccinated and unvaccinated exposed to the infection of small-pox in invaded houses we find some interesting figures. At ages below ten, the vaccinated had a twenty-three-fold immunity from attack and a complete security against death as compared with a mortality among the unvaccinated of 11·5 per cent. At ages above ten the vaccinated had a three-fold immunity from attack and a ten-fold immunity against death as compared with the unvaccinated. As an instance of the protective value of vaccination performed after exposure to small-pox, it may be mentioned that of 59 unvaccinated persons exposed to the disease, 23 were vaccinated on or before the fifth day of exposure, 3 seven days after exposure, and 1 not until after the eighth day; in the last 4 cases, as the writers observe, no protection could probably be claimed from vaccination. Of the total 27 none contracted small-pox, whereas of the remaining 32 unvaccinated persons more than half developed the disease. The value of re-vaccination is shown by the figures that follow. Out of 1341 persons remaining in the invaded houses 468 were successfully revaccinated, and 8 only—all of whom showed that they had been infected before revaccination—contracted small-pox. The attack-rate among the 859 once vaccinated was 5 per cent. In the remaining 14 the attempted revaccination was unsuccessful, and of these, 3 developed small-pox and 1 died. Among the hospital staff of 62 persons there were 3 cases of small-pox; of these one was that of a person not revaccinated and another a case in which revaccination had been performed fourteen years previously; both recovered. The third case was that of a washerwoman at the small-pox hospital, who had been vaccinated twenty years previously, and who had passed through several epidemics with impunity. She was unfortunately not included in the revaccinated list, and she died from hæmorrhagic small-pox. This sad result illustrates, the writers of the report point out, the necessity for the repetition of vaccination, especially in persons hourly exposed to contagion. As bearing upon this question may be related the fact that during the Bristol epidemic of 1893–94 there were 7 cases of small-pox in those who had been previously attacked by the disease, the shortest interval between the attacks being twenty-five years and the longest sixty-nine years; none were fatal.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 5930 births and 3949 deaths were registered during the week ending Oct. 5th. The annual rate of mortality in these towns, which had increased from 19·3 to 21·0 per 1000 in the three preceding weeks, declined again last week to 19·4. In London the rate was 15·9 per 1000, while it averaged 21·9 in the thirty-two provincial towns. The lowest rates in these towns were 13·2 in Croydon, 14·2 in Huddersfield, 14·4 in Brighton, and 14·6 in Derby; the highest rates were 26·6 in Liverpool, 28·8 in Sunderland, 30·3 in Salford, 32·3 in Bolton, and 37·2 in Blackburn. The 3949 deaths included 871 which were referred to the principal zymotic diseases, against 981 and 923 in the two preceding weeks; of these, 565 resulted from diarrhœa, 71 from diphtheria, 65 from "fever" (principally enteric), 64 from measles, 56 from whooping-cough, 48 from scarlet fever, and 2 from small-pox. The lowest death-rates from these diseases were recorded in Norwich, Croydon, Derby, and London, and the highest rates in Sunderland, Oldham, Salford, Bolton, and Blackburn. The greatest mortality from measles occurred in Oldham, Salford, and Blackburn; from scarlet fever in Gateshead and Wolverhampton; from whooping-cough in Bradford, Bolton, Wolverhampton, and Gateshead; from "fever" in Leicester and Sunderland; and from diarrhœa in Salford, Oldham, Burnley, Bolton, and Blackburn. The 71 deaths from diphtheria included 44 in London, 4 in West Ham, 4 in Salford, and 3 each in Birmingham, Liverpool, and Manchester. One fatal case of small-pox was registered in London and 1 in Oldham, but not one in any other of the thirty-three large towns. There were 198 cases of small-pox under treatment in the Metropolitan Asylum Hospitals and in the Highgate Small-pox Hospital on Saturday last, the 5th inst., against 307, 271, and 234 at the end of the three preceding weeks; 17 new cases were admitted during the week, against 42, 23, and 21 in the three preceding weeks. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 2802, against 2674, 2732, and 2807 on the three preceding Saturdays; 252 new cases were admitted during the week, against 365, 344, and 339 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had increased in the three preceding weeks from 123 to 173, declined again last week to 158, and were 79 below the corrected average. The causes of 30, or 0·8 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Bristol, Nottingham, Salford, Sheffield, Newcastle-upon-Tyne, and in fifteen other smaller towns; the largest proportions of uncertified deaths were registered in Birmingham, Leicester, and Liverpool.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight principal Scotch towns, which had been 18·5 and 17·5 per 1000 in the two preceding weeks, rose again to 18·3 during the week ending Oct. 5th, but was 1·1 per 1000 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 16·5 in Edinburgh and 17·5 in Dundee to 20·6 in Perth and 21·1 in Paisley. The 527 deaths in these towns included 62 which were referred to diarrhœa, 17 to whooping-cough, 8 to "fever," 4 to scarlet fever, 3 to measles, 2 to diphtheria, and not one to small-pox. In all, 96 deaths resulted from these principal zymotic diseases, against 93 and 79 in the two preceding weeks. These 96 deaths were equal to an annual rate of 3·3 per 1000, which was 0·9 below the mean rate last week from the same diseases in the thirty-three large English towns. The fatal cases of diarrhœa, which had declined from 78 to 48 in the five preceding weeks, rose again to 62 last week, of which 27 occurred in Glasgow, 9 in Edinburgh, and 7 in Dundee. The deaths from whooping-cough, which had declined from 15 to 9 in the four preceding weeks, rose again to 17 last week, and included 10 in Glasgow and 4 in Aberdeen. The deaths referred to different forms of "fever," which had been 10 and 6 in the two preceding weeks, increased to 8 last week, of which 3 occurred in Glasgow and 2 in Dundee. The 4 fatal cases of scarlet fever were within one of the number in the preceding week, and included 3 in Glasgow. The deaths referred to diseases of the respiratory organs in these towns, which had been 66 and 82 in the two preceding weeks, further rose to 98 last week, and exceeded by 35 the number in the corresponding period of last year. The causes of 49, or more than 9 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 22·1 and 24·8 per 1000 in the two preceding weeks, declined again to 21·3 during the week ending Oct. 5th. During the thirteen weeks of last quarter the death-rate in the city averaged 23·4 per 1000, the rate during the same period being 18·6 in London and 16·5 in Edinburgh. The 143 deaths registered in Dublin during the week under notice showed a decline of 23 from the number in the preceding week, and included 12 which were referred to the principal zymotic diseases, against 21 and 24 in the two preceding weeks; of these, 8 resulted from diarrhœa, 2 from scarlet fever, 1 from small-pox, 1 from whooping-cough, and not one either from measles, diphtheria, or "fever." These 12 deaths were equal to an annual rate of 1·8 per 1000, the zymotic death-rate during the same period being 2·6 in London and 1·9 in Edinburgh. The deaths referred to diarrhœa, which had been 12 and 13 in the two preceding weeks, declined to 8 last week. The fatal cases of scarlet

fever, which had been 2 in each of the two preceding weeks, were again 2 last week. The mortality from small-pox and from whooping-cough showed a decline from that recorded in the previous week. The 143 deaths in Dublin last week included 28 of infants under one year of age, and 28 of persons aged upwards of sixty years; the deaths both of infants and of elderly persons showed a marked decline from those recorded in the preceding week. Eight inquest cases and 7 deaths from violence were registered; and 38, or more than a fourth, of the deaths occurred in public institutions. The causes of 6, or more than 4 per cent., of the deaths in the city last week were not certified.

VITAL STATISTICS OF LONDON DURING SEPTEMBER, 1895.

In the accompanying table will be found summarised complete statistics relating to sickness and mortality during September in each of the forty-three sanitary areas of London. With regard to the notified cases of infectious disease in the metropolis during last month, it appears that the number of persons reported to be suffering from one or other of the nine diseases specified in the table was equal to 12·4 per 1000 of the population, estimated at 4,392,346 persons in the middle of the current year. In the three preceding months the rates had been 8·4, 11·6, and 9·9 per 1000 respectively. Among the various sanitary areas the rates were considerably below the average in Fulham, St. James Westminster, St. Martin-in-the-Fields, St. Olave Southwark, Woolwich, and Lee; while they showed the largest excess in Strand, St. Luke, Bethnal Green, Whitechapel, St. George-in-the-East, Limehouse, Mile End Old Town, and Poplar. The prevalence of small-pox in London showed a marked decline during September, 117 cases being notified during the month, including 23 in Bethnal Green, 13 in Camberwell, 11 in Whitechapel, 11 in Lambeth, 9 in Islington, and 8 in Battersea sanitary areas. The Metropolitan Asylum Hospitals contained 227 small-pox patients at the end of September, against 33, 232, and 331 at the end of the three preceding months; the weekly admissions averaged 27, against 10, 49, and 57 in the three preceding months. The prevalence of scarlet fever in London showed a marked increase during September; this disease was proportionally most prevalent in Strand, Holborn, Clerkenwell, St. Luke, City of London, Bethnal Green, Whitechapel, St. George-in-the-East, Limehouse, and Mile End Old Town sanitary areas. The Metropolitan Asylum Hospitals contained 2745 scarlet fever patients at the end of September, against 1845, 2340, and 2435 at the end of the three preceding months; the weekly admissions averaged 333, against 229, 263, and 292 in the three preceding months. The prevalence of diphtheria in London also showed a considerable increase during the month under notice; among the various sanitary areas this disease showed the highest proportional prevalence in St. Pancras, Bethnal Green, St. George-in-the-East, Limehouse, Mile End Old Town, Poplar, and Camberwell. There were 664 cases of diphtheria under treatment in the Metropolitan Asylum Hospitals at the end of September, against 633, 680, and 666 at the end of the three preceding months; the weekly admissions averaged 101, against 109, 103, and 80 in the three preceding months. The prevalence of enteric fever in London showed a marked increase during September; this disease was proportionally most prevalent in Marylebone, Stoke Newington, Hackney, Shoreditch, Bethnal Green, Limehouse, Mile End Old Town, Poplar, and Camberwell sanitary areas. Erysipelas was proportionally most prevalent in St. Giles, Strand, St. Luke, and Mile End Old Town sanitary areas. The 14 cases of puerperal fever notified during September included 3 in Greenwich and 2 in Marylebone sanitary areas.

The mortality statistics in the accompanying table relate to the deaths of persons actually belonging to the various sanitary areas, the deaths occurring in the institutions of London having been distributed among the different sanitary areas in which the patients had previously resided. During the four weeks ending Saturday, Sept. 28th, the deaths of 5393 persons belonging to London were registered, equal to an annual rate of 16·0 per 1000 of the population, against 14·9, 21·0, and 16·9 in the three preceding months. The lowest death-rates during September in the various sanitary areas were 11·0 in Strand, 11·4 in Lee, 11·5 in Wandsworth, 11·7 in Paddington, 12·2 in Stoke Newington and in Lewisham, and 12·3 in St. George Hanover-square and in Hampstead; the highest rates were 20·2 in Mile End Old Town, 21·0 in St. George Southwark, 21·1 in St. Saviour Southwark, 21·2 in Whitechapel, 21·4 in Shoreditch, 23·9 in Holborn, 25·4 in St. George-in-the-East, and 25·6 in St. Luke. During the four weeks of September 983 deaths were referred to the principal zymotic diseases in London; of these, 449 resulted from diarrhœa, 185 from diphtheria, 117 from measles, 77 from whooping-cough, 76 from scarlet fever, 67 from enteric fever, 11 from small-pox, and 1 from an ill-defined form of continued fever. These 983 deaths were equal to an annual rate of 2·9 per 1000; the lowest zymotic death-rates were recorded in Hampstead, Stoke Newington, St. Martin-in-the-Fields, Holborn, St. Olave Southwark, and Lewisham; and the highest rates in St. Luke, Whitechapel, St. George-in-the-East, Mile End Old Town, St. Saviour Southwark, St. George Southwark, and Woolwich sanitary areas. Eleven fatal cases of small-pox were registered in London during the month under notice, the corrected average in the corresponding periods of the ten preceding years being only 3; of these 11 fatal cases 2 belonged to Lambeth and 2 to Camberwell sanitary areas. The 117 deaths referred to measles were 46 above the corrected average; among the various sanitary areas this disease showed the highest proportional fatality in St. Pancras, Clerkenwell, St. Luke, Whitechapel, Limehouse, and Mile End Old Town. The 76 fatal cases of scarlet fever were 21 below the corrected average number; this disease showed the highest proportional fatality in Shoreditch, Bethnal green, and Whitechapel sanitary areas. The 185 deaths referred to diphtheria were 40 above the corrected average number; among the various sanitary areas this disease was proportionally most fatal in St. Pancras, Clerkenwell, Bethnal Green, St. George-in-the-East, Mile End Old Town, St. George Southwark, Lambeth, and Greenwich. The 77 fatal cases of whooping-cough were 47 below the corrected average; this disease showed the highest proportional fatality in Fulham, Shoreditch, and Newington sanitary areas. The 67 deaths referred to enteric fever slightly exceeded the corrected average number; among the various sanitary areas the highest proportional fatality of "fever" was recorded in Hackney, Mild End Old Town, St. George Southwark, Rotherhithe, and Woolwich. The 449 fatal cases of diarrhœa were 77 above the corrected average; this disease was proportionally most fatal in St. Giles, Whitechapel, St. George-in-the-East, Limehouse, St. Saviour Southwark, Bermondsey, Woolwich, and Plumstead sanitary areas. In conclusion, it may be stated that the mortality in London during September from these principal zymotic diseases was rather more than 12 per cent. above the average.

Infant mortality in London during September, measured by the proportion of deaths under one year of age to registered births, was equal to 162 per 1000, and slightly exceeded the average. Among the various sanitary areas the lowest rates of infant mortality were recorded in Paddington, Islington, Strand, London City, St. Olave Southwark, and Rotherhithe; and the highest rates in Westminster, Holborn, Whitechapel, St. Saviour Southwark, St. George Southwark, and Plumstead.

THE SERVICES.

MOVEMENTS OF THE MEDICAL STAFF.

SURGEON-MAJOR-GENERAL LEWER has arrived in England from Gibraltar on retirement and will be succeeded by Surgeon-Colonel Catherwood. Surgeon-Captain Holt has been transferred from Aldershot to Sheerness. Surgeon-Major Inman has arrived from Barbados on leave. Surgeon-Captain Fletcher has arrived at Gibraltar. Surgeon-Lieutenants Smith, Blackham, and Fairrie have been posted to Aldershot; Surgeon-Lieutenants Forrest and Fawsett to Portsmouth; Surgeon-Lieutenants Greech and Grattan to Ireland; Surgeon-Lieutenant Profeit to Edinburgh, and Surgeon-Lieutenant Gunter to Shorncliffe.

INDIA AND THE INDIAN MEDICAL SERVICES.

Surgeon-Lieutenant C. B. Prall, 36th Sikhs, is appointed to officiate as Civil Surgeon of Peshawar, in addition to his other duties, vice Surgeon-Major B. Doyle, on leave. Surgeon-Major J. W. Clarkson is appointed to act as Sanitary Commissioner for the Government of Bombay during the absence on leave of Brigade-Surgeon-Lieutenant-Colonel C. W. MacRury. Surgeon-Major C. G. W. Lowdell is appointed to act as Deputy Sanitary Commissioner for the Western Registration District, in

Digitized by Google

addition to his own duties, from the date of Surgeon-Major J. W. Clarkson giving over charge. The services of Surgeon-Captain W. D. Sutherland and Surgeon-Captain H. E. Banatvala, which were placed temporarily at the disposal of the Chief Commissioner of the Central Provinces under the Home Department Notifications, are placed permanently at the disposal of the Chief Commissioner.

ARMY MEDICAL RESERVE OF OFFICERS.

The undermentioned Surgeon-Lieutenant-Colonels having exceeded the limit of age laid down in Article 663, Royal Warrant July 6th, 1895, cease to be Officers of the Army Medical Reserve of Officers:—Alexander R. Mackenzie, M.D., Thomas F. Greenwood, and Henry F. Holland, M.D., The undermentioned Surgeon-Lieutenants to be Surgeon-Captains:—John M. H. Martin, M.D., F.R.C.S. Eng., and David Todd.

MILITIA MEDICAL STAFF.

Surgeon-Lieutenant-Colonel T. F. Greenwood, 4th Battalion the Sherwood Foresters (Derbyshire Regiment), retires, with permission to retain his rank, and to wear the prescribed uniform on his retirement.

NAVAL MEDICAL SERVICE.

Staff-Surgeon John Anderson McAdam is promoted to the rank of Fleet-Surgeon.

The following appointments are notified:—Surgeons: S. H. Youel to the *Champion*, and T. C. Hickey to the *Repulse*.

VOLUNTEER CORPS.

Royal Engineers: 2nd West Riding of Yorkshire (Leeds): Surgeon-Captain C. Richardson to be Surgeon-Major. The Severn Division: Surgeon-Lieutenant W. L. Edwards to be Surgeon-Captain. *Rifle:* 4th Volunteer Battalion the Cameronians (Scottish Rifles): Surgeon-Lieutenant W. G. Marshall, M.B., resigns his commission. 1st (Inverness-shire Highland) Volunteer Battalion the Queen's Own Cameron Highlanders: Surgeon-Lieutenant W. de Watteville, M.B., to be Surgeon-Captain.

THE FRENCH IN MADAGASCAR.

It does not yet seem to be absolutely certain that the news of the capture of the capital of Madagascar and the flight of the Queen from Antananarivo is reliable. The French people have every reason, however, to hope and believe that General Duchesne's force has by this time reached and captured Antananarivo. The expedition was dispatched in the spring of this year and consisted of 15,000 men. The troops disembarked at Tamatave, a port on the north-east coast. The losses from fighting have been insignificant, the Hova army having offered little or no opposition to the French. Sickness arising from the bad climate on the coast, the difficulties of the march, the employment of troops in road-making, and the want of proper arrangements have been the principal causes of the grave losses that have attended the expedition. Antananarivo is some 4000 feet above the sea level, has a population of 100,000, and is a fairly well built city. It is said to be, and owing to its elevation most probably is, healthy. The sanitary state of General Duchesne's advanced force in the uplands is reported to be excellent. The French have no doubt had to encounter very serious obstacles and topographical as well as climatic difficulties. Once the troops get into quarters in the capital and are protected during the rainy season we may confidently expect better accounts. The invaliding arrangements do not seem to have been good, the losses on shipboard during the transit of the troops from Madagascar to France having been serious.

VOLUNTEER MEDICAL SERVICE.

Surgeon-Lieutenant-Colonel M. Baines, V.D., writes to us suggesting that, in the event of a commission being appointed to consider the various questions raised by the commanding officers of the Volunteer force, a request should be made for a small annual grant for the stretcher bearer section of each regiment. Ambulance work is not only important in times of war, but a knowledge of it even in times of peace is of considerable value, and the small grant suggested—namely, 7*s*. per efficient bearer—is insignificant when compared with the important *rôle* which stretcher bearers would play in case of war. The grant would be expended in providing all ambulance requisites and appliances necessary for the proper and satisfactory teaching of the various classes.

THE CAMPAIGN IN CUBA.

According to a Central News telegram there is a good deal of sickness among the Spanish troops in Cuba. Yellow fever is stated to be increasingly prevalent. Five hundred men have succumbed to that disease since March last, and there are 1000 patients in the various local hospitals.

THE NAVAL MEDICAL SUPPLEMENTAL FUND.

At the quarterly meeting of the directors of the Naval Supplemental Fund, held on the 8th inst., Inspector-General T. Russel Pickthorn in the chair, the sum of £48 was distributed among the several applicants.

CADET BATTALIONS.

1st Cadet Battalion the Norfolk Regiment: Acting Surgeon H. W. Crosse, M.B., resigns his appointment.

Correspondence.

"Audi alteram partem."

"'RETURN' CASES OF SCARLET FEVER."

To the Editors of THE LANCET.

SIRS,—The origin of so-called "return cases" of scarlet fever, an instance of which forms the subject of a letter from Dr. Paget Thurstan in your last issue, is a matter of practical importance to the community apart from its purely scientific interest. In ascribing the source of infection to the nightgown which was handed to the mother on the return of the child after nine weeks' detention in hospital Dr. Thurstan appears to claim an explanation which the facts of the case hardly warrant. While expressing his belief that disinfection of the nightgown had been thoroughly and efficiently carried out, Dr. Thurstan inclines to the view that the linen had again become infected by its having been dried in an atmosphere charged with infection owing to its immediate proximity to the fever hospital. The explanation is, in view of collateral evidence, difficult to accept; for if the air in the drying-ground were infectious to this degree it would go hard with the inhabitants of the neighbouring tenements of which the backyards, in respect of one large fever hospital, abut on the hospital premises. The yards referred to not only serve as the playground of the numerous young children living in these houses, but in them on washing day is invariably to be seen the household linen hanging out to dry. The distance separating the yards from the windows of the scarlet fever wards is only five or six yards—an interval considerably less than that which intervenes between the wards and the laundry drying-ground in most fever hospitals. Contrary, however, to what might be expected if the validity of Dr. Thurstan's belief be accepted, the incidence of scarlet fever amongst the inhabitants of these houses is no greater than it is in the parish at large. The experience derived from all fever hospitals goes to show that the infection of scarlet fever is incapable of transmission for any distance in the open, and there is little doubt that its rapid loss of virulence is to be ascribed to the destructive influence of light and air.

If we assume the infection of a "return case" to have been derived from the previous one, and are content to put aside the chance of coincidence in respect of an external source, there are certainly two modes of infection which, in most cases, are deserving of careful consideration. First, there is the possibility of some infected article having accidentally escaped disinfection at the hands of the sanitary officials, however careful they may have been in the discharge of their duties. On receipt of the news that the child is to be discharged from the hospital this article of clothing, book, or toy is forthwith brought out of the cupboard or drawer in which it has been lying and may then for the first time be in a position to infect some other member of the household. It is true that this channel of infection may be accountable for but few of the "return cases," but that it may be a practical factor is strongly suggested by the not very infrequent instances in which a second case arises within a few days of the *expected* return of the first, although the patient, owing to some cause or other, may have had to be detained for a further period in hospital and have not been sent home until a later date—in fact, not until after the second case has arisen. We never hear of this being quoted as a "return case" however. Even if it is possible to eliminate

Digitized by Google

this source of infection with certainty in Dr. Thurstan's case, there yet remains another very important one—viz., the patient himself, and it is quite possible that he may be the direct source of infection, coming, as he does, straight home from the ward of a fever hospital. The infectivity of scarlet fever desquamation is generally accepted, and also the danger attaching to the slightest discharge from either the ears or nose, which, in the opinion of those best qualified to form an opinion, is a far more fertile source of infection than the later desquamation. The belief is slowly gaining ground that even a healthy person, after a prolonged residence in a scarlet fever ward, is capable of imparting contagion by means of his breath for several days at least after passing out of his infected environment.

Until the day comes when a sterilisation of the respiratory passages of a living person becomes a practical possibility it is to be feared that "return cases" will from time to time occur. The remedy would seem to lie in a further isolation of the child for several days after his return home; but to provide the accommodation necessary to carry this out on a rational basis in respect to every patient before his discharge from the public fever hospitals would entail too heavy a burden upon the ratepayer.—I am, Sirs, yours truly,

F. FOORD CAIGER.

Fever Hospital, Stockwell, S.W., Oct. 8th, 1895.

"OVER-OPERATING IN GYNÆCOLOGY."

To the Editors of THE LANCET.

SIRS,—Mr. Lawson Tait would, I am sure, not wilfully mislead your readers, but his memory has been so inaccurate in reference to a case in which he mentions my name that I hope you will allow me to correct his statement. In a letter published in your columns on Sept. 21st he says: "We had under our joint care a lady who had a bleeding myoma and immense wealth. I had recommended removal of the appendages, a course not approved of by Sir William Priestley and not favoured by the patient and her friends, and therefore not pressed by me. The result was she remained under my care (occasionally when death from hæmorrhage was imminent joined by Sir William), and in bed most of the time, for about thirteen years, when the climacteric relieved her from the severe symptoms at the age of sixty-three or four. During that time her illness cost thousands of pounds, a proportionate share of which fell to the lot of Sir William Priestley and myself. If I had operated on her—with a bagatelle risk of 1·6 per cent. mortality—I should have had probably 150 guineas and Sir William Priestley about as much more at the end of a successful case (and I do not think a fatality would have altered the amount), or somewhere about a fifth of what we actually did get." The facts are these. 1. I met in January, 1881, Mr. Lawson Tait and the patient's medical man in the country to see a lady who had a moderate-sized myoma, and whom I had twice before seen in London. The patient was then fifty-three years of age, and, although still suffering from hæmorrhage, did not seem to me so much worse as to demand an operation. 2. In January, 1884, three years later, she came to London and then assured me that she had quite recovered some time before. The pain and hæmorrhage had ceased, and the myoma had almost disappeared. The patient was then fifty-six years of age and going about as usual. She is now sixty-seven and in good health. 3. I only saw the patient professionally once after my consultation with Mr. Tait, and this was alone in London. I received the ordinary fees for my visits, and, therefore, if thousands of pounds were expended in medical attendance they did not come to me.

I am, Sirs, yours sincerely,

WILLIAM O. PRIESTLEY.

Hertford-street, Mayfair, Oct. 5th, 1895.

To the Editors of THE LANCET.

SIRS,—The exceeding rancour with which Mr. John Frederick Bullar persecutes his next-door neighbour at Southampton confuses his mental perception. The mortality percentage I estimated for my case is obtained from a long series of similar cases (removal of the appendages for myoma), published in 1890, for of that series it would have formed one if operative measures had been adopted. Its mortality has nothing to do with the 15 per cent. of deaths in a series of cases of all kinds in the earliest practice of Mr. Bullar's neighbour. Again, Mr. Bullar forgets that removal of the appendages in these cases reveals no disease whatever in them in the great majority of cases, so that if he does know of such innocent appendages having been removed in Southampton, is he sure that there was no disease in the uterus for which the operation was done? On these three points Mr. Bullar has blundered; and, as he was one of my pupils, it is a great blow to my vanity that he attacks the doctrines of his master with paper clubs, doctrines of which at one time he knew so much and of which he was so proud.

I am, Sirs, yours faithfully,

7, Crescent, Birmingham, Oct. 7th, 1895. LAWSON TAIT.

"HOSPITAL ABUSE AT BRIGHTON."

To the Editors of THE LANCET.

SIRS,—With all due regard to the invaluable space in your columns I will ask you to allow me to briefly reply to the correspondents who have written refuting my statements on the abuse of hospitals at Brighton. According to both Dr. A. J. Richardson and the secretary of the Sussex County Hospital, 4 per cent. of the cases which were treated were not entitled to charity. This makes a total of 408 in one year for one hospital alone, which at the same ratio for all the other hospitals would amount to a considerable figure and give a living to three or four medical men. I quite admit that the hospitals most abused are those which are devoted to the treatment of special diseases. No one knows the extent of that abuse better than the general practitioner, and no investigation could be complete that does not include their evidence. In my original letter I stated that over one-third of the women who gave birth in 1894 were attended by one charity alone, and that does not include those attended in the union, or the others by the society for helping women in their first fall. Is it possible for so many women to be paupers? I do think that the Lying-in Institution should give some explanation, and I should like also to hear the opinion of the resident medical officers who have been attached to that charity. One of the midwives made a statement a short time ago that in her experience at least half the applicants were in a position to pay for private medical attendance. In your excellent leading article of Jan. 26th of this year you assert what is beyond dispute—namely, that if this gigantic system of abuse was stopped there would be ample means to meet the needs of the deserving poor. Though the wealth of the nation on the whole is progressing, and the position of the working man greatly improved, the increased figures of out-door and in-door attendances at our hospitals would, if the cases were all deserving of charity, go to prove that pauperism is in the ascendency. This matter may not affect those medical men who have been many years in practice in the town, but what about the young men struggling for a living in the paths of an honourable profession—have they not to be considered? I trust that our hospitals will go on extending their inestimable blessing to the poor in the hour of their sickness or injury, but let us at the same time face a great evil and see that charity is not misapplied. I am, Sirs, yours truly,

Hove, Oct. 7th, 1895. FRANCIS J. A. WARING.

"THE PHYSIOLOGY OF DEATH BY ELECTRIC SHOCK."

To the Editors of THE LANCET.

SIRS,—I have read with great interest Dr. Richard C. Shettle's second letter in THE LANCET of Sept. 28th upon "The Physiology of Death by Electric Shock." There is one point, however, which is not quite clear to me, and upon which I should like to ask for information. After very clearly describing the theory according to which "it is probable that the diamagnetic molecules in the living body are continuously rotating upon a definite axis, the axis of rotation in every case being determined by the relation which each form of matter has to the magnetic force," Dr. Shettle goes on to say: "In fact, it is clear that, under the known relations which exist between matter and the magnetic force, the only influence which magnetism can exercise upon the living body is to render the polarity of every atom engaged in the maintenance of life more marked, and therefore more capable of maintaining the phenomena which are naturally

Digitized by Google

evolved during life by the material elements." I venture to think that this can only be true as long as the living body is so placed in the magnetic field that the polarity induced by the latter coincides with the normal polarity of the molecules composing the former, and that, supposing Dr. Shettle's theory to be correct, it would be quite possible so to place the living body in relation to the magnetic field that the polarity induced by the one would be in direct opposition to that inherent in the other. Dr. Shettle considers, if I have followed his reasoning correctly, that this antagonism can result only in the deviation of the molecular axes from their original direction, much in the same way that a suspended magnetic needle is deflected upon the approach of a magnet, and that such deviation would have no appreciable effect upon the organism. Now, granting for a moment that no more complex result might be expected from the opposition of similar magnetic poles, is it reasonable to suppose that such a radical change of direction as the one under consideration could take place without causing some very distinct modification of the natural functions of the body? The fact that no such modification actually occurs when the living body is introduced into the most powerful magnetic field—no matter in what position the one may be placed in relation to the other—would appear, I think, to tell very strongly against the validity of Dr. Shettle's theory. I make these suggestions with the utmost reserve and solely with the object of obtaining information upon a subject in which I am much interested. At the same time, I am fully aware that the apparent difficulty may be owing entirely to my own imperfect knowledge and consequent failure to grasp the facts under consideration with the necessary clearness.

I am, Sirs, yours faithfully,

Hornsey, Oct. 5th, 1895. W. B. FOTHERINGHAM.

"PRECEPTS FOR CYCLISTS."

To the Editors of THE LANCET.

SIRS,—In the annotation on the above subject contained in the last issue of THE LANCET you unreservedly condemn the inclined posture adopted by the conventional "scorcher" on the ground of its being detrimental to health. Speaking as a cyclist of many years' experience, I have never been able to understand why this particular position should be condemned on hygienic grounds. I readily admit that it is ungraceful in the extreme, but it is certainly an error to suppose that it "rounds" the shoulders. On the contrary, the shoulders are held stiffly back in order to obtain a firm grip for the extraordinary muscles of respiration, and the bend is a hinge movement at the axis of the hip-joint and not a forward curvature of the spinal column. The error has probably arisen from the fact that this position throws into prominence any existing tendency to "round shoulders," in the causation of which it takes, however, no part. From a physiological point of view the "forward bend" is the best, in that it enables the rider greedy of speed to develop a maximum degree of effort with a minimum of distress. The truth of this statement is evidenced by the fact that all of us intuitively follow the "scorcher's" example under strain, as when climbing a hill or facing a head wind.

I am, Sirs, yours faithfully,

Oct. 7th, 1895. ALFRED S. GUBB, M.D. Paris.

"SKETCHES FROM RHENISH WATERING-PLACES."

To the Editors of THE LANCET.

SIRS,—Your Berlin correspondent omits to mention one of the most charming of the health resorts of the Rheingau. Having spent a month there this summer, I may perhaps be allowed to give your readers a brief account of Schlangenbad It is seven miles from Wiesbaden, four from Schwalbach, both of which are reached by carriage, and four from Eltville, where all the Rhine boats stop. There is now a steam tramway between Eltville and Schlangenbad, so that it is reached with the least possible trouble. The village lies in the forests of the Taunus, the surroundings are beautiful, walks through the woods having been carefully laid out in every direction, to Rauenthal (one mile and a half), Georgenborn (the same distance), and many other picturesque villages. There are a pretty little Kursaal, seven "Kurhäuser," several good hotels, and the expenses are very moderate. The baths are delicious; the chemical composition and medicinal properties of the waters have been fully described by the resident physician, Dr. Baumann. They seem specially suited to cases of neurasthenia or irritable nervous conditions, which respond very quickly to Schlangenbad treatment. It may have been the property of the baths or the early hours, regular life, and the restfulness of the sheltered walks, but more probably the result of all these factors, that produced such a rapid improvement in the neurotic patients that were sent there. Eczema and other skin affections were quickly cured by the baths. As far as I was able to judge these two classes of patients got the greatest advantage from Schlangenbad. For medical men and their families it is a charming pleasure resort, and easily reached. They are admitted free to the baths and are exempt from Kur tax. Shooting (stag, partridge, &c.) can easily be obtained in the neighbourhood; also good music, pleasant society, absolute rest if desired, or excursions in all directions, good food, and capital accommodation. What more could be desired either for summer holiday or health resort? All these advantages, and more, can be obtained in Schlangenbad. I am, Sirs, yours truly,

West Brighton, Oct. 7th, 1884. W. G. THISTLE.

ADVERTISING IN HIGH PLACES.

To the Editors of THE LANCET.

SIRS,—I see by the daily press that Dr. —— and also Dr. —— have returned to their respective homes after a brief holiday. As the leading men of the profession persist in setting such a noble example of professional etiquette to their humbler brethren, I intend in future to make a black list of these advertising gentlemen for my private use only, and to refrain from sending any of my patients to them when I desire the advice of a consultant. I think that if other general practitioners would do the same it might influence these gentlemen to some extent in self-advertisement. I am, Sirs, your obedient servant,

Oct. 8th, 1895. M.R.C.S.

HOTELS AND INFECTIOUS DISEASES.

To the Editors of THE LANCET.

SIRS,—I venture to ask you for the following information. Should a patient fall ill with diphtheria in a large and crowded London hotel, would he, after the case had been duly notified to the authorities, be compelled to leave the hotel at a few hours' notice and to be taken to the fever wards of a hospital? Would the patient or his family, if they refused to leave the hotel, be liable to be sued before court for damages caused to the hotel (in guests leaving &c.)? I have been placed in a very anxious position by a case of this kind happening to an English patient of mine at a Zürich hotel, and should be very glad to know how the authorities act in England under the same circumstances.

I am, Sirs, yours faithfully,

Oct. 1st, 1895. TURICENSIS.

*** There is no universal rule in England. Many provincial towns have no infectious hospitals to which such cases could be removed either compulsorily or voluntarily. And even where such hospitals exist, including the metropolis, there is no power of compulsory removal unless a magistrate's order for such removal is procured. The magistrate can issue this order on one or other of three conditions: 1. That the patient is "without proper lodging and accommodation." 2. That the patient is in a room occupied by members of more than one family. 3. That the patient is on board a ship. The first condition would be the one affecting a hotel, but the legal interpretation placed on it varies very much, some saying that the question of proper lodging, &c., must be decided on grounds of protecting the public; others, with probably more correctness, declaring that in view of the second condition it is the propriety of the lodging *qua* the patient that is in question, except where the room holds persons of another family. But, as a matter of fact, such cases are very generally, though not always, removed from hotels into hospital; for the London Fever Hospital has private rooms, which go far to remove the objection of the better classes to isolation in hospital.—ED. L.

AURI SACRA FAMES.

To the Editors of THE LANCET.

SIRS,—On returning to town after the vacation I met with a remarkable incident which seems to me to claim attention. The Royal Colleges of Physicians and Surgeons most liberally placed free of cost the Examination Halls on the Embankment at the disposal of the British Medical Association for the meetings of sections for reading and discussing scientific subjects. I hear, for I was not present, that almost the entire ground floor of this large building was occupied as a vast advertising ground for all kinds of drugs, instruments, &c.—so vast that the advertisers paid £1200 or £1500 to the Association. Of course, the Colleges are not responsible for this proceeding; their assent was not asked, and they have not received, and could not accept, any of the proceeds. The Colleges will no doubt take some notice of the matter when they meet. In the meantime allow me to suggest that the money thus obtained by the British Medical Association should be devoted to scientific purposes or given to some of the medical charities; at least, it cannot pass without question into the coffers of the Association.

I am, Sirs, yours obediently,

Oct. 5th, 1895. MEDICUS.

THE DRAINAGE OF PORTSMOUTH.

(FROM OUR SPECIAL CORRESPONDENT.)

MANY years have now passed since a general scheme for the drainage of Portsmouth was planned and carried out. This was done in 1866, and since that date the population of the town has greatly increased and sanitary science has made considerable progress. It is not probable that in these days the plans for draining Portsmouth which were accepted some thirty years ago would meet with approval. Judged in the light of modern science, extraordinary blunders were committed. The drainage scheme consisted of a high and a low level system. Both had their outfall in front of Fort Cumberland into the Langston Channel, where the sewage is rapidly carried out to Spithead. The high level system discharged by gravitation at the ebbing tide, and the sewage in the low level system had to be pumped up into the high level outfall. Both systems meet at a point to the east of the town called Highland Cottage and thence travel on to the pumping station, the low level main drain being five feet under the high level sewer. But even with the aid of the pumping the gradients are absurdly insufficient. It will scarcely be credited, but for a distance of 6685 feet the fall is barely equal to six inches in a mile; yet so as to secure even this mere semblance of gravitation there are parts of the main sewers which are only just under the surface of the streets. From 1866 to 1881 no less than 20,550 houses were connected with these sewers, and their inefficiency soon became manifest. A great portion of the main sewers were converted into sewage reservoirs. Here the sewage stagnated and formed deposits pending the time when the tide would be favourable to its discharge into the sea. Thus there was no constant flow in the sewers, and when heavy rains fell the sewers overflowed and flooded the basements of the houses. Then the sewers, already too small for the rapidly increasing population, became choked up by the sand and the deposits of all sorts which must naturally accumulate when sewage is allowed to stagnate. If to this is added the fact that improvement was necessary with respect to the scavenging or cleansing of the sewers by work of hand, it will be seen that the state of affairs would become absolutely intolerable. In 1881 the local authority were obliged to advertise for schemes likely to effect an improvement. Finally a proposal to build reservoirs was made by Sir Frederick Bramwell and adopted. Just by the outfall and in front of Fort Cumberland reservoirs that will hold 4,500,000 gallons have been constructed. As these discharge twice a day this means a total amount of 9,000,000 gallons of sewage that can be dealt with in the twenty-four hours before the sewers themselves become a reservoir for the holding of stagnant sewage. Under these circumstances the flow of the sewage should not be interrupted. Nevertheless, though these reservoirs have considerably improved matters, the drainage is still unsatisfactory. The gradients remain altogether insufficient and therefore the sewers are very far from being self-cleansing. Then some of the sewers were built of such porous material that a very large quantity of sea water percolates through their walls. With spring tides the low level sewers, that are little better than mere sieves, have brought down to the pumping station 3,000,000 gallons of sea water. The town has been put to the expense of raising this enormous volume of sea water, not a drop of which ought to have gained admittance to the sewers. When the cost in the wear and tear of expensive machinery and the consumption of valuable fuel which the raising of 3,000,000 gallons of water involves are considered it will be realised what an extravagant waste is thus occasioned.

Owing to the presence of a large quantity of sea water in the sewers and the increase of population and the area drained, there is, especially during heavy rains, more sewage than the reservoirs can hold. Consequently, of two evils one must occur: either the sewers must again become reservoirs holding stagnant sewage or else some of the sewage must be discharged into the sea at unsuitable periods of the tide. But even if this difficulty at the outfall did not exist, still the drainage would not be properly effected, because the sewers are too small for the large volume of water which now reaches them during heavy rains. The gradients being so slight, the sewage cannot flow with sufficient rapidity to the outfall to relieve the more distant portions of the town. Therefore the sewers will be found to be quite full in one part of the town, while nearer to the outfall they are only two-thirds full. Last autumn a number of cellars were flooded in the town and this at a time when the main sewer near the outfall was only two-thirds full. Then at one place where the main sewer receives sewage from three local collectors the main sewer is so small that it can only hold half the amount of sewage which the three collectors are capable of delivering. It is as if one tried to empty two pints into a one-pint measure. Under the stress of these circumstances, and at the suggestion of the borough engineer, Mr. Philip Munch, a sum of £30,000 has been voted and is now being expended so as to deal separately with the rain water. Some eight or nine years ago a separate system was instituted in the Stamshaw district. This was a newly created quarter covering some thirty acres of ground adjoining the Landport district. The method adopted is to drain the rain water from the streets and from the front roofs and fronts of the houses into a separate sewer which has its outfall at the nearest convenient point, either in the harbour or in the sea. The water from the backs of the houses and the backyards, which is likely to be fouler, together with the domestic drainage or sewage proper, will continue to flow into the old sewers. Only the cleanest portion of the rain water will reach the supplementary or separate sewers that are in course of construction. It is confidently expected that this rain water will be clean enough not to cause any nuisance in the harbour or on the beach. An outfall at Flathouse will discharge into the harbour the drainage of eighty acres of roadways and frontage. The drainage from ninety acres of frontage and roads will fall into the Camber, and thence will flow to the harbour mouth. Forty more acres of Portsea and forty acres of the old town of Portsmouth will also be thus drained into the Camber. The distances being short the difficulty of obtaining proper levels is not great. Where the natural levels are insufficient a gradient for such short distances can be created by digging deeper in the roadways. Catch-pits are contrived to prevent sand and grit from entering these sewers. In the districts where the system has been already applied it has worked well and caused no inconvenience. When thus in part relieved from the pressure of rain water it is anticipated that the old drainage system of Portsmouth will work much better, and that the distress caused by the flooding of cellars and basements by sewage will be avoided. Nevertheless, the drainage of the town can never be satisfactory so long as the sewers are not self-cleansing; nor can they become so while the gradients are too slight to admit of a rapid flow of the sewage. There is but one way of draining a flat town, and that is by raising the sewage frequently and at short intervals. There must be, not one pumping station, but many pumping or raising stations. Then, if the pumping stations are near enough, a gradient may be created by digging down to these various elevating stations. It is most unfortunate that so important a town as Portsmouth should have been drained, and this at a great expense, in a manner that was not in keeping with these fundamental principles, for it seems as if the work will sooner or latter have to be done all over again.

Portsmouth.

THE BATTLE OF THE CLUBS.

(FROM OUR SPECIAL COMMISSIONER.)

(*Continued from p. 877.*)

"SWEATING" MEDICAL MEN AT LINCOLN.

A MEDICAL SOCIETY was formed at Lincoln in the year 1863. This society met once in the winter. Scientific papers were read, and then the members had supper with the president. In the summer the members met again, went to the country, and had a picnic. This was very pleasant, but it scarcely constituted a bond of union of sufficient strength to resist the encroachments of the formidable benefit societies that flourish at Lincoln. Now, however, the medical society meets once a month, and not only are scientific papers read, but professional interests are discussed. The subject of the benefit clubs has been for some time a matter frequently mentioned; but as some of the members of the Medical Society are sometimes called in to consult with the benefit club medical officers they did not altogether approve of the energetic manner in which these institutions were attacked. Nevertheless, as the grievance became more and more evident, the necessity of taking action was ultimately acknowledged. On Feb. 27th last Dr. Mounsey called attention to the fact that many opulent tradesmen were obtaining medical aid from the benefit clubs, and it was decided to hold a general meeting of the whole of the profession in and about Lincoln on March 8th. At this meeting a resolution was adopted and sent to the British Medical Association; and a petition signed by all present was sent to the General Medical Council. Twenty-five Lincoln practitioners and nine practitioners from the surrounding districts signed this petition. It was worded as follows and sets forth briefly the grievances of the Lincoln practitioners, whose signatures follow:—

"To the General Council of Medical Education and Registration.

"GENTLEMEN,—We, the undersigned general practitioners of the city of Lincoln and neighbourhood, humbly beg to call the attention of the General Medical Council to the following facts, viz.:—

"1. That there are in Lincoln two medical aid associations called the United Friendly Societies and the Manchester Unity of Oddfellows, employing respectively three and two qualified practitioners at fixed salaries.

"2. That these medical officers do not receive the full amount paid by the members for medical attendance.

"3. That these associations canvass for members.

"4. That a large number of leading tradesmen and well-to-do men of independent means avail themselves of the advantages of these institutions at the low rates of 3*s.* 6*d.* per annum per member, with an addition of 8*s.* per annum for wife and any number of children under the age of sixteen.

"5. That the number of these institutions is on the increase, and obtains not only in this city but in the clubs in the neighbouring villages.

"We submit that this state of matters is calculated to degrade the medical profession, and we humbly pray that your honourable Council will frame measures to check these abuses.

(Signed)

"G. Mitchinson,	John T. Collier,
J. G. Watkins,	Fred. S. Gurney,
W. A. Carline,	Fred. S. Lambert,
Leslie H. Revill,	E. Mansel Sympson,

W. J. Cant,	F. J. Mason,
T. H. White,	A. E. Boot,
C. Harrison,	Godfrey F. R. Lowe,
J. H. Pim,	Arthur H. Lowe,
G. H. Mounsey,	G. Parson Forney,
F. C. P. Howes,	S. R. Deane,
Charles G. Dalton,	Osborne Johnson,
F. Bastow Cooper,	Henry Johnson,
Wm. Swan,	J. D. Cambell,
Edward C. Palmer,	C. Brook,
George S. Boulton,	G. M. Lowe."

In answer to the above petition the officials of the General Medical Council sent three copies of the minutes of evidence taken on the question when the Council held an inquiry on this subject some three years ago. In this connexion it is important to bear in mind that, when the various benefit societies federated together to form the Lincoln United Friendly Societies Dispensary, they requested the General Medical Council to send a representative to see that the new system of medical aid should be organised on proper lines. The position here at Lincoln is altogether different from what I have described as existing at Portsmouth and at Eastbourne. At Lincoln five medical men are employed exclusively by the Manchester Unity of Oddfellows and by the United Friendly Societies Dispensary. These medical men receive a fixed salary and are not allowed to have any private practice. Now when this system was first instituted the representative of the General Medical Council especially stipulated, and it was agreed, that no profit should be made out of the work of the medical men employed by these benefit societies. It is, however, easy to prove, from published balance sheets, that this condition has not been observed and that profits have been made out of the medical men. It was understood that the managing committees were to work for nothing, or, in any case, were not to pay themselves out of the fees given for medical aid. The General Medical Council should know that this rule, which they themselves established, has not been observed. Facts and figures bearing on this point were published by the *Lincolnshire Echo* of Feb. 15th, 1895, which quotes the THE LANCET on this subject. Then I find in the sixteenth annual report of the Friendly Societies' Medical Alliance that, in the year 1894, the Manchester Unity of Oddfellows had 4889 members in Lincoln who, between them, had in the course of the year 24,173 medical consultations, 31,431 prescriptions, and 6934 medical visits. There were 58 deaths. The subscriptions paid for medical aid amounted to £989, though the amount received by the medical men was only £381. The dispensers were paid £116, cab fares absorbed £65, drugs £161, and £32 were paid to the secretary, treasurer, and committeemen. This equals a total expenditure of £758 and leaves a balance on the receipts of £231. The two medical men in the service of this society naturally expected that this sum would be divided between them, since it was stipulated that no profit should be made out of the medical men. This, however, has not been done. The Manchester Unity of Oddfellows has simply pocketed a large proportion of the money made by the medical men in its service. This profit has been literally sweated out of the two medical officers. These officers had given, in the course of the year, 31,107 consultations and visits, and they have received for this enormous amount of work £384. These show that they have been attending patients for an average fee of a fraction under 3*d.* per visit or consultation. By paying them only £384 the society has made a profit of £231. The profits sweated out of the medical officers amount to nearly two-thirds of the sum it paid them. The sweating Jew tailors in the East-end of London do not make as much out of their victims, and yet it was agreed with the representative of the General Medical Council that no profit should be made out of the medical men. Further, it should be noted that I have reckoned in this calculation the £32 given to the secretary, treasurer, and committee as legitimate working expenses, though it had been understood that the committees should work for nothing.

The United Friendly Societies Dispensary employs three medical officers. They had in 1894, children included, 4396 members. The medical officers gave 16,763 consultations, 27,255 prescriptions, and 7815 visits. There were 40 deaths. The receipts amounted to £917; the salaries to the three medical men were £478, £57 were paid to the dispenser, £48 were spent in cab fares, £186 in drugs, and £14 in fees to the secretary, treasurer, and committee. Thus the total expenditure was £783, and as the receipts are set down at £917 it would seem that the net profits amounted to £134. To produce this profit the medical men in the service of this society have had to give consultations and advice at an all-round average of a fraction above 4½*d.* per visit or consultation. It is surely time that some authoritative expression of opinion should be obtained as to this sweating of profits out of the underpaid labour of medical men. It may well be asked how the dignity of the profession can be maintained under such conditions. At the other towns I have visited the average amount received per consultation was as low, in some instances, as 4*d.*, but the remuneration, such as it was, all went to the medical officer, and the society did not make a profit out of it. Also the medical officer derived indirect advantages—his club work brought him private practice which paid much better; while here at Lincoln the five club medical officers are by their contract debarred from accepting private practice. Further, if the number of members increases their work increases in due proportion, but their salaries do not increase, nor do they enjoy any measure of independence. They are the paid servants of a society represented by a committee, and are ever at the beck and call, not of one master, but of a whole committee. If any member thinks he has been neglected the medical officer has to appear before this committee, and a body of tradesmen and workmen

Digitized by Google

sits in judgment upon him and decides whether he has treated a medical case with proper discernment and attention. How can such a committee express an opinion on such a subject? Many a practitioner, after a little experience of this sort of work, has thrown up the post in disgust; but there are others who are not in a position to venture on following this good example.

If the medical officers are poorly paid, the sum allowed for drugs is not more liberal. On a previous occasion THE LANCET pointed out that the £161 paid by the Manchester Unity at Lincoln for 31,431 prescriptions meant an average of a fraction over a penny per bottle for medicine, and expressed the opinion that this seemed "hardly compatible with power and effect in dealing with the varied and often dangerous phases of disease." Thereupon Mr. William Coulson, secretary of the Lincoln Oddfellows' Medical Institution, wrote to the *Lincolnshire Echo* that drugs of the very best quality only were purchased from one of the best wholesale houses in the country. He added that the medical officers' instructions from the committee were not to spare expense, but to provide the patients with the medicaments they required. This does not, however, do away with the fact that many patients are treated with a few stock prescriptions which are kept ready made up and which usually contain cheap and ordinary remedies. It could not be otherwise. Even if money was forthcoming for special prescriptions there would not be time to write out a prescription, and still less time to have it made up. There are often sixty, and sometimes eighty, patients waiting for advice at these dispensaries. There may be two medical men to receive them, but often there is only one medical man present. Indeed, I was assured that one of the medical officers had said that he had seen sixty patients in an hour. The more carefully this matter is studied the more evident it will become that the grievances are not only on the side of the medical men. Reform is urgently needed, not only in defence of the reputation and material interests of the medical profession, but also for the sake of the members, especially the poorer members, of the benefit societies themselves.

Lincoln, Oct. 7th.

(To be continued.)

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

The Manchester Museum.

THE subject of a grant to the museum was resumed at the last meeting of the City Council. It may be remembered that several years ago the Natural History Museum, as it was called, obtained an asylum at Owens College at considerable cost to the College, and that the Corporation was memorialised several months ago for a grant in aid of its maintenance. The Free Libraries Committee recommended a grant of £400 a year if the county councils of Lancashire and Cheshire and some of the local district councils would give £800. An amendment was moved, and has been accepted by the committee, that this condition should not be attached to the grant. It was discouraging to observe the narrow and short-sighted view taken by several members of the council as to the value of such an institution to the people of Manchester and the district round, illustrating, as the museum does, every branch of natural history in its widest sense. One who had been a city father for ten years had only known of the museum in connexion with Owens College since the question was introduced. Another said "there were museums enough in Manchester," though as to where they would be found he did not enlighten the council, but he showed his special fitness to give an opinion by saying "he had never been in the museum at all." It will scarcely be believed but this gentleman has had all the advantage he could derive from an average middle-class education. It was said, moreover, "the museum was not one that would attract the masses of people; it was merely a museum for students." No doubt the masses might be more attracted by steam-organs and merry-go-rounds, but they are provided elsewhere. Then, too, the raising of the rates that would be caused by this £400 divided among 500,000 people, and the grave prospect of "setting a dangerous precedent," were duly held forth *in terrorem*. And so this humiliating discussion proceeded. Alderman Thompson said truly "there was nothing more painful than this exhibition of utter indifference on the part of the council to higher education." He showed that the museum was really for the public, and was not required for the students of the College. "The medical men did not need it because they had a museum of their own, and the arts people did not need it, neither did the electricians nor the chemists, because they also had museums of their own." He contrasted Liverpool with Manchester greatly to the disadvantage of the latter, showing that the former gave grants to various departments of higher education of £1800 a year, while "the Owens College authorities were taunted because they asked for a miserable £400 a year." The discussion was again adjourned for a fortnight.

Gift to the Free Library.

It must not be supposed from the above-mentioned discussion in the City Council that Manchester has no regard for science or literature. The late Mr. Alexander Ireland, who died some short time since, was a great lover of literature and had a wide acquaintance with the literary men of the last generation. He had a special fondness for the works of Hazlitt, Leigh Hunt, Lamb, Carlyle, and Emerson, and with most of these authors he was on terms of personal friendship. He was a diligent collector, and left at his death 360 volumes of their writings, with various manuscripts, including the original one of Mrs. Ireland's life of Mrs. Carlyle. They were bought by Mr. T. R. Wilkinson, who has generously presented them to the Free Library. In his letter to the chairman of the committee he says: "I wish to present this collection, with the book-case which holds it, to my native city; and I venture to express the hope that it may be kept together in the city library as a memorial of our late dear old friend and citizen, Alexander Ireland."

Manufacture of Explosives.

The City Council was somewhat exercised at its last meeting as to the proposed establishment of an explosives factory in Ardwick, a densely populated part of Manchester. An application for a licence led to a local inquiry, when it was decided that such a licence ought not to be granted. The tradesmen, shopkeepers, and property owners believed that a great danger would be caused by the carrying on of such a manufacture in their midst. The applicants appealed to the Home Secretary, who came to the decision, "in accordance with the opinion of his technical advisers," that there would be no risk of explosion, "but at the worst of conflagration," "with the variety and quantity of nitro-cotton to which, by the draft licence, Messrs. Moseley are limited." The Watch Committee protested, and justified their objections to the licence by the general alarm and by the depreciation in the value of the surrounding property. It was moved and carried that the Home Secretary should be further communicated with. The insurance offices are evidently not of the opinion of the "technical advisers," for it is said that notices have been sent to the neighbouring business men and property owners of an increase of 50 per cent., and in one case of 100 per cent., in their insurance premiums. It seems rather hard for the neighbourhood to be exposed to increased risk of fire, and so to increased risk of life, even if the technical advisers think they will not be blown up. But in yesterday's papers Messrs. Moseley say that the preparation they make and use of collodion cotton is not explosive, and is only in a slight and slow degree inflammable. The material to be manufactured is called pegamoid, and is said to be of almost universal application in connexion with the textile fabrics. They say that Colonel Majendie, the Chief Inspector, came down and saw the buildings, the mode of manufacture, and the article pegamoid in its various preliminary states and in its finished condition. Shortly afterwards they heard the licence was confirmed, so that presumably he was satisfied. But this morning's papers contain letters from important firms which seem to show there are just grounds for alarm. It seems that permission has been obtained to store 800 lb. of gun-cotton, and if the "small fires" which Messrs. Moseley admitted at the public inquiry had happened should again occur the people of Ardwick may be excused for feeling some anxiety. There is a feeling in the council that the Home Office should not have thus over-ridden the action of the Watch Committee.

Medical Dinner.

The annual dinner of the Owens College and the Manchester Royal Infirmary was held on Thursday last at the Queen's Hotel, under the presidency of Mr. G. W. Mould. The Lord Mayor of Manchester and the Mayor of Salford,

Digitized by Google

Mr. E. S. Heywood (chairman of the Infirmary Board), Alderman J. Thompson (treasurer of the Owens College), Mr. J. W. Maclure, M.P., and Dr. Robert Maguire, an old Manchester student, were among the guests. In proposing the toast of "The Lord Mayor and Corporation of Manchester and the Mayor and Corporation of Salford," Mr. Mould took occasion to remark how greatly the health and happiness of the community depended on those important sanitary measures, provident and protective, which were so ably devised and carried out by our local legislators. The toast of "The Manchester Medical School" was responded to by Professor Young, the Dean, who referred to the unrivalled facilities for work given by the new buildings and to the very large entry of medical students this session. Mr. Thomas Jones, professor in surgery, in speaking to the toast of "The Manchester Royal Infirmary," contrasted the present building with the modern palatial structures found in almost all other large towns, as, e.g., Liverpool and Derby, and suggested that the enterprise which produced the Ship Canal and brought water from Thirlmere should give to Manchester a building worthy of the city. Dr. Little proposed "Our Guests," which was responded to by Mr. Maclure and Dr. Robert Maguire. The health of "The President" was proposed with much grace and feeling by Mr. E. S. Heywood, and was most enthusiastically received. Mr. Mould's reply was followed by some music, and a very pleasant evening came to a close.

A Police-constable and First Aid.

Mr. Gilbert has said, "A policeman's lot is not a happy one," so that one is glad to record anything that may tend to lighten it. An inquest was held on Friday last, at the Eccles and Patricroft Hospital, on the body of a man who had been run over after falling from a lorry. He was seriously injured about the left thigh, and Police-constable Crawford, who was near at hand, promptly rendered first aid by stopping the bleeding, and then removed him in the mail-coach from Manchester, which was passing at the time, to the hospital, where amputation was found to be necessary. But the man sank and died next morning. The jury returned a verdict of "Accidental death," and added that they desired to express their high appreciation of the prompt and skilful first aid rendered by Police-constable Crawford, "by means of which the deceased's life was probably prolonged until efficient medical aid could be procured." They further recommended his action to the notice of the Chief Constable.

Manchester Sewage.

The Mersey and Irwell joint committee yesterday granted a further period of six months to Manchester for the completion of her sewage scheme. From a statement made by the city surveyor it seems that "the amount actually paid up to the 19th ult. by the Corporation was £556,540 17*s.* 3*d.* The total estimated cost of the existing works was £700,000, and, roughly speaking, there was about £100,000 worth of work in course of construction." If no difficulties were met with it would take at least twelve months to complete the work. A portion of the sewage is treated at the filter beds at Davyhulme, and Sir H. Roscoe said the effluent was of an exceptionally good character, for not only was the whole of the polluting organic matter destroyed, "but the water contained what was always looked upon as a sign of purity, a certain amount of free oxygen." Formerly the sewage had flowed continuously on to the filter beds, but now after some hours the flow was stopped and the air allowed to percolate through the mass. "This appeared to be essential to get the right action of the nitrogenous microbes, which really did the work." There is also in operation a costly and elaborate plant for the chemical treatment of the sewage and for sludge pressing, and additional land has been reserved for future tank extension if the present tank capacity should be found insufficient. At present thirty acres are devoted to the filter beds—not enough to deal with the whole of the sewage; but the Local Government Board has sanctioned the sum of £25,000 for the construction of the first section of artificial filters on sixty additional acres, which, according to the experts, will be sufficient. The construction of two experimental filters has been sanctioned in order to have a practical demonstration of the treatment of the Manchester sewage on the system proposed by the London County Council. The London sewage reaches the works at Barking in a putrid condition, and it is a question not yet decided as to whether the system is equally applicable to the sewage of Manchester, which enters the works in a practically fresh state.

Oct. 8th.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

Royal Infirmary, Newcastle-on-Tyne: the Site Question.

THE town council has decided, and almost unanimously, to refuse the request of the governors of the infirmary for an extension of their present site, on the grounds that the accommodation for the pigs and sheep would be curtailed. Many people in Newcastle are of opinion that the cattle market should be removed from the centre of the town, but the present members of the town council evidently do not think that it would be advantageous. Not so very long ago a bull in one of the main thoroughfares of the town gored a boy, tearing out parts of three or four ribs, opening up his pericardium and exposing his heart. In another instance a bull thrust his horn into the knee-joint of a lad and tore it open, necessitating amputation of the limb. Both these cases were treated in the infirmary, but very little was heard of them or of other severe and sometimes fatal accidents due to the driving of cattle through the main thoroughfares of the city. No doubt if the mayor or other prominent citizen had been the unfortunate victim a good deal would have been heard of the inconvenience and danger of continuing to hold a large cattle market in the very centre of a populous city. In its annotation upon the action of the town council the *Newcastle Daily Journal* writes: "We agree with Mr. Alderman Richardson and Alderman Stevens that the tone and attitude of the council towards the infirmary are much less sympathetic than they ought to be. It may be quite true that the council is not officially concerned in finding a new site for the infirmary, but morally there is no higher responsibility devolving upon it than to assist an institution like this in performing its invaluable functions in an efficient manner. The finances of the institution are not in a condition to allow of an expensive site being acquired, and unless the corporation grant its assistance the work of the infirmary must be crippled." The city council always expresses its anxiety to help the infirmary in its present strait; hitherto the outcome of its desire to assist has been that it has refused every application made to it, and last week it determined not to appoint any member of its body to form a joint committee with representatives from the infirmary committee to confer together as to the best method of procuring a new or an enlarged site, on the ground that it was no part of the town council's duty to provide, or to assist in providing, a site for the infirmary. This is a very different spirit to that which animated the town council 150 years ago; then a site was given to the infirmary by the corporation. The position the town council is now taking up is not, to say the least of it, a sympathetic one.

Destruction by Fire of the Old Mansion House, Newcastle-on-Tyne.

During the evening of Sunday, Oct. 6th—the anniversary, curiously enough, of the great fire in the same locality thirty-one years ago—the old Mansion House was found to be on fire. It was in use as a storage for oil, and in it were 1000 barrels of oil. Fortunately, with the exception of some timber in immediate proximity which was burnt, no damage, beyond the destruction of the building and its contents, was done. The old Mansion House, including a valuable collection of City plate and an extensive cellar of wine, was sold by auction in the year 1837. The ancient building was a quay-side feature, and is immortalised in John Shield's well-known song of "My Lord Size."

Newcastle-on-Tyne.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Lunacy in Scotland.

THE recent report of Mr. Carswell, certifying physician under the Barony Parish Council, Glasgow, contains further evidence in support of the statement that lunacy is not increasing in Scotland out of proportion to the growth of the population. The Barony parish includes a very extensive area, and the social condition of those inhabiting it is marked by great steadiness; indeed, it was selected some little time ago by Sir Arthur Mitchell as the district most suitable for the purpose of conducting an exhaustive inquiry into the alleged increase of insanity. Mr. Carswell's statistics show that though the number of certified lunatics has

Digitized by Google

risen from 135 in 1890 to 148 in 1895, the corresponding proportions per 100,000 of population are 44·7 and 45·1. The conclusions are practically identical with those arrived at by Sir Arthur Mitchell, whose inquiry embraced the ten years from 1883 to 1892. There are two reasons which combine to explain the increased number of pauper lunatics. In the first place it is shown that the lunatics do not as a rule recover to such an extent as to justify their discharge, whilst under the present system of treatment their lives are prolonged.

Glasgow Medico-Chirurgical Society.

The first meeting of this society for the session 1895–6 was held on the 4th inst., the President, Dr. W. L. Reid, being in the chair. It was decided to record an expression of regret at the death of Dr. J. H. Carslaw, who had reported the proceedings of the society in the *Glasgow Medical Journal* during the last four sessions. Dr. C. O. Hawthorne showed—(1) a brain with a recent hæmorrhage into the pons and cerebellum; (2) a female patient aged eleven years with considerable enlargement of the spleen, the history showing recurrent attacks of purpura, but none of the incidents usually associated with splenic enlargement; and (3) a man in whom the left brachial artery divided some distance above the level of the elbow-joint, the ulnar artery from this abnormally high origin passing in front of the muscles arising from the internal condyle and the fascia of the forearm. Dr. Hinshelwood read a paper on Word Blindness and Visual Memory, in which he narrated two cases he had seen, there being in one patient blindness to letters but not to figures, whilst the other suffered from object blindness.

Resignation of a Medical Officer.

Mr. W. A. Algie, Portpatrick, has intimated to the parish council his resignation as medical officer of the parish.

Home for Infirm Children, Glasgow.

In the annual report of the medical officer, Mr. Wilson Bruce, it is stated that the children admitted during the past year have on the whole been more acutely ill than in previous years, and that the deaths have consequently been more numerous; at times, too, there has been great pressure on the accommodation provided. A considerable piece of ground adjacent to the home has recently been purchased by the directors, and it is intended in December next to hold a bazaar with a view to improve the financial position of the home.

Faculty of Physicians and Surgeons, Glasgow.

At a meeting of the Faculty on the 7th inst. Mr. John Brown, M.D., and Mr. John M. Munro Kerr, M.B., having passed the necessary examinations and been elected, were admitted Fellows of the Faculty.

The Pollution of the Gareloch.

The Dumbarton county council some months ago appointed Mr. F. C. Buchanan, convener of the Public Health Committee, and Dr. John C. McVail as a sub-committee to report upon the condition of the foreshores of the Gareloch, one of the most picturesque of the lochs communicating with the estuary of the Clyde. These gentlemen have just issued an elaborate report, in which they find that the insanitary state of the foreshore is due to—(1) drainage from the dwelling-houses on the shores of the loch and (2) pollution by vessels anchored in, or plying on, the loch. They express the opinion that some remedy must speedily be found if the district is to maintain its position as a residential neighbourhood and favourite summer resort, and recommend that the Secretary for Scotland should be petitioned either to declare the loch a stream under the Rivers Pollution Act or to sanction by-laws giving the local authority power to prevent the deposit of solid refuse on the foreshore and the introduction of untreated sewage into the loch. This report has been adopted by the county council.

Aberdeen District Nursing Association Bazaar.

The total receipts at this two days' bazaar amounted (including £404 10*s.* 6*d.* of donations) to £1506 11*s.* 6*d.* Lady Gordon Cathcart opened the bazaar on the first day. On the second day Lady Kintore performed this function, being introduced by Dr. Angus Fraser, President of the Association. A vote of thanks was passed to Dr. Fraser. The Marchioness of Lorne sent a number of valuable gifts. In one of the two drawings—that for a picture of a Surrey landscape—Dr. Marshall, North Queensferry, was the winner.

Oct. 8th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The New Dublin Hospital for Infectious Disease.

AT a meeting of the guardians of the Rathdown Union on the 2nd inst., Viscount Powerscourt, K.P., in the chair, a letter was read from the Public Health Committee, Dublin, requesting the guardians to send a deputation to the conference which is to be held in the office of the committee at Cort's-hill, on Thursday next, Oct. 10th, "to consider the advisability of erecting a hospital in some rural district for the purpose of isolation in cases of infectious disease." A deputation, consisting of five of the guardians with their medical officer, Dr. Hamilton, was appointed to attend the conference. The necessity for the proposed hospital is now fully recognised, for, although the fever hospital at Cork-street was of immense service to the inhabitants of Dublin during the recent epidemic of small-pox, the undesirability of having an institution situated in a crowded part of the town for isolation of infectious disease is shown by the facts which have recently transpired, from which it would appear that, notwithstanding every precaution, the area of the city surrounding that hospital suffered more severely from the disease than elsewhere.

The Children's Hospital, Temple-street, Dublin.

The Medical Board at their last meeting appointed Mr. Herbert Mooney, M.B., F.R.C.S.I., to be ophthalmic surgeon to the institution.

A New Dublin Dispensary.

At a meeting of the guardians of the South Dublin Union on the 3rd inst. a letter was read from the Local Government Board in reference to the proposed erection of a new dispensary at Castle-street, which stated that the building, as shown by the plans, was of too elaborate a character for the requirements of the district. Its cost, as was noted, would probably amount to £4000, which would entail an annual payment of over £200 on the district. The Local Government Board requested the guardians to reconsider their proposed plans, and apparently with good reasons, for many complaints have been made of late years by the highly-taxed citizens of South Dublin, while it is notorious that many of them have ceased to rent houses in the city and removed to the adjoining townships. The consideration of the letter was adjourned until the next board meeting.

The Amalgamation of Irish Poor-law Unions.

At the present time in Ireland the whole question of the Poor-law management is causing very great discussion. In THE LANCET attention has been already drawn to the union infirmaries, but another point is cropping up and is being ventilated in the public press and boards of guardians, and that is the amalgamation of the Poor-law unions. There can be no doubt that the amalgamation of neighbouring unions would cut down very much present expenses, a matter of no small moment just now in a country like Ireland, where agricultural depression is making the rural lot of the taxpayers a very heavy one. In favour of this policy of amalgamation it may be pointed out that the number of inmates in many of the provincial unions is much smaller than the number for which the workhouses were originally built. Thus, as pointed out by a writer in the *Freeman's Journal*, there were at the commencement of the year (September, 1893, to September, 1894) in the Lisburn Union 144 inmates in a workhouse originally built for 800; 230 in Armagh, which was built for 1000 inmates; and 382 in Tralee, which can accommodate 1000. Again, the question of expenditure for the indoor maintenance of the residents and the cost of salaries and rations bears a curious relationship. Thus in Ulster the indoor maintenance is £65,851, while the salaries and rations of officers cost £32,919; in Munster the relationship is £120,464 to £46,742; in Leinster, £131,469 to £46,823, while in Connaught it is £34,736 to £17,973; in other words, the total sum spent in Ireland on the salaries and rations of officers in the four provinces is £144,457, while that spent on indoor maintenance is £356,520, or, to put it another way, the cost of the salaries is about 40 per cent. of the actual cost of indoor relief. It is evident, therefore, that if there was amalgamation of two adjacent unions which are now not at all full, probably in many cases without any enlargement of the existing buildings one of

Digitized by Google

these workhouses would accommodate all the inmates, and there would be an immense saving in the expense of salaries. At present if a union desires amalgamation with a neighbouring one the guardians apply to the Local Government Board, who send down an inspector to take evidence, which he lays before the Local Government Board, who have the power to issue an order for the amalgamation of the two unions if they think it desirable. Of course, to this system of amalgamation of unions there are the obvious objections that those in the employment of the unions must be thrown out of work, and undoubtedly this would have to be met by the consideration of vested interests. But one thing is evident—a complete change will have to be made in the present Poor-law system in Ireland, and if Mr. Gerald Balfour grants a commission to consider the matter the subject of the amalgamation of unions will undoubtedly be thoroughly considered. In the cities such as Dublin and Belfast the workhouses are much more crowded (indeed, some would say overcrowded) than in the provincial districts.

The Report of the Treasury Committee on the Retirement of Professors of the Irish Queen's Colleges.

Some of the evidence given before the committee recently inquiring into the question of the retirement of Queen's College professors is of considerable importance to the medical profession. It may not be generally known that medical professors who engage in private practice are not entitled to pensions, on the ground that they do not devote the whole of their time to the College, though, as one witness pointed out, the council of the College can and does call on them to give all the time to their professorial work which the interests of the College may require. Emphasis was also laid on the fact that the practical experience gained by those professors whilst engaged in their private practice is a very distinct advantage to the College, as it enables them all the more readily to keep pace with the advance of medical science; and it was very aptly suggested that the clinical hospital is to the medical professor what the laboratory or museum is to the Arts professor. It is very gratifying to find that the three presidents and the professors representing the three colleges were all unanimous in urging that justice should be done to the medical professors in the matter of pensions. This is all the more remarkable as none of the witnesses are directly connected with the medical faculties of the colleges. The evidence of Dr. Moffatt, President of the Galway College, was particularly valuable. After expressing his own opinion very forcibly he mentioned that the Rev. Osborne Gordon of Oxford, Mr. Herbert Murray of the Treasury, and Professor Allman, the Professor of Natural History at Edinburgh, were members of a Commission issued in the year 1876 to enquire into the condition and working of the Queen's Colleges and he gave the following extract from their report strongly urging that medical professors of the colleges ought to be entitled to pensions: "In an earlier portion of this report we stated that we saw no reason for increasing the stipends of the legal and medical professors, but that we thought it advisable that a claim to a retiring allowance should be admitted, as in the case of the Scotch Universities, irrespective of the question whether or not the whole time of the professors was given to the public. We are aware of the sound rule which has been established in the Civil Service under which a pension-right only accrues in those cases in which the public have a claim to the whole time of the servant; but we think that the essence of that rule lies in the fact that the public gains by the energies of its servants being centred on their public duties, while a liberal provision is made for retirement on the approach of age or on the failure of the faculties. But in the case of the professors of law and medicine the reverse is the case. The public is the direct loser if their activity is limited to their college life, and professional practice—the larger the better—is actually essential to sound and efficient teaching. It is also an objection to the present system that in Ireland, especially in the west—where the emoluments of a practice are comparatively small and where the salary of a chair is therefore of greater importance—the temptation of a pension in the future might possibly outweigh the immediate advantages of a practice, and that thus the restriction which is nominally imposed in the public interest might induce a professor to impair his efficiency as a teacher by abandoning the practice of his profession. At the same time, one of the main objects for which retiring allowances are granted seems to be overlooked, inasmuch as retirement in consequence of impaired efficiency never is and never will be enforced in the absence of pensions; professors past their work are continued in office and the public in consequence continue to pay full salary for inadequate and inefficient service. On these grounds we are of opinion that the rule which renders engagement in professional practice incompatible with a claim to a retiring allowance should be reconsidered in the case of the Queen's College professors, and that, as is the case in the Scotch universities, they should after reasonable service and under proper conditions be entitled to pension whether engaged in professional practice or not."

Oct. 8th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Funeral of Monsieur Pasteur.

LAST week I gave your readers full particulars of the life and career of the great man who has been removed from our midst; to-day I must say a few words about the national demonstration of sorrow on the occasion of the removal of his remains from the Institute that bears his honoured name to the metropolitan Cathedral of Notre Dame. It may be said that one national funeral in Paris resembles another, but, with the exception of Victor Hugo, no personage in this country who was neither a soldier nor a statesman has been so honoured as was Louis Pasteur on Saturday last. Thousands of citizens of all grades of society visited the Institute to take a last look at the venerated features of him whom they acknowledged to have been the greatest known benefactor of suffering humanity. I will not attempt to describe the progress of the procession, but some idea of the proportions and importance of the cavalcade may be gathered from the fact that the magnificent funeral car, drawn by six horses, was escorted by no less a force than two infantry divisions, two regiments of artillery, and an entire cavalry brigade, under the command of General Saussier, Governor of Paris, and Generals Madelor and de Saint-Julien. At 10.15 A.M. the body was placed in the car, while on the coffin were placed the cocked-hat, coat, and sword of the deceased Academician. Headed by the band of the Garde Républicaine, playing Chopin's funeral march, the immense body of mourners wended their way to the Cathedral, General Saussier and his staff, followed by the First Infantry Division, taking precedence. Among the mourners were representatives of musical and gymnastic societies, syndicates, vast brewing interests, agricultural societies, humane societies, and numerous municipalities, including that of Paris, Dôle (his native place), and Arbois; deputations from the École Normale, École de Physique et de Chimie, École des Beaux-Arts, École Commerciale, &c.; students from Norway, the University of Salamanca, the Collège de l'Arc (Dôle), and from Russia; members of the Association Générale des Étudiants de Paris, in their Tam-o'-Shanters; the *internes des hôpitaux;* deputations from the Academy of Medicine of Medellin (Columbia), the Pasteur Institute of Havana, the Edinburgh University, and the Medical Society of London; and representatives of numerous learned French societies, including several Faculties of Medicine and the Professors of the Alfort Veterinary School. Wreaths of all sizes were carried in profusion, the names visible on them being, amongst others, Laboratoire Municipal, Préfecture de la Seine, Préfecture de Police, Conseil Municipal, &c. The hearse was loaded with floral tributes emanating from the Institut Pasteur ("A son chef"), the Duke of Orleans, the Laboratory of Experimental Pathology of the Paris Faculty, the Berliner Medicinische Gesellschaft ("ihrem grossen Ehrenmitglied Louis Pasteur"), the Experimental Institute of St. Petersburg, the University of Liége, the Pasteur Pavilion of the Cochin Hospital (Paris), the Association of Foreign Students of Paris, Portugal *reconnaissant*, the Toulouse Medical Faculty, the Service de la Diphtérie à l'Hôpital des Enfants Malades (Paris), the Distillers of France, &c. Then followed three immense wreaths, the first of natural flowers, bearing the inscription "A Louis Pasteur—le Roi de Portugal," the second composed of everlastings from the École Polytechnique (accompanied by a delegation of students in uniform), and the third of orchids and foliage, "A Pasteur—le Gouvernement de la République." The pall-bearers were M. Poincaré (Minister of Public Instruction), M. Bertrand (Permanent Secretary of the Academy of Sciences), M. Perrot (Director of the École

Digitized by Google

Normale), M. Brouardel (Dean of the Paris Faculty of Medicine), M. Boissier (Permanent Secretary of the Académie Française), and M. Bergeron (Permanent Secretary of the Paris Academy of Medicine). The Royal College of Physicians of London were represented by their treasurer, Sir Dyce Duckworth. Then followed the deceased's son and son-in-law and other relatives, Madame Pasteur having proceeded directly to the Cathedral. After the family walked Commandant Bourgois, representing the President of the Republic (who awaited in person the arrival of the procession at Notre Dame), the President of the Council, the Foreign Minister, the Minister of the Interior, the Minister of War and of Marine—in fact, all the Ministers excepting one absent from Paris. The Corps Diplomatique, the two Houses of Parliament, the Legion of Honour, the Institut de France, officers of all arms, the Conseil d'Etat, Cour de Cassation, Cour d'Appel, clergy of all recognised denominations, &c., all were represented. Twelve mourning coaches and about a hundred private carriages followed, the enormous procession being closed by the Second Infantry Division, the cavalry, the artillery, a half-squadron of the Mounted Republican Guard, and a platoon of police. The entire distance covered by the procession was lined by troops, and the attitude of the immense crowds looking on was respectful in the extreme, every man uncovering and many women making the sign of the cross as the hearse passed. The *catafalque* upon which the remains were placed in the choir of Notre Dame was the same as was used at the funeral of the murdered President Carnot. The President of the Republic was seated in the prechoir, the officiating clergy being the Cardinal-Archbishop of Paris, the Archbishop of Sens, and the Archpriest of Notre Dame. Behind the President were the Grand Duke Constantine, Prince Nicholas of Greece, the Ministers, &c. The mass over, the coffin was transported to a *catafalque* erected in the square in front of the church and facing the Hôtel Dieu. Here, in the presence of the President and the family, M. Poincaré delivered a speech reviewing the scientific career of the illustrious dead. The following extracts from the Minister's admirable discourse merit transcription:—

"Les phrases les plus émues ne sont qu'un éloge bien médiocre devant la pieuse douleur que cette perte irréparable a provoquée dans la France entière et qui a rassemblé aujourd'hui, sur le passage de ce funèbre cortège, vieillesse et enfance, richesse et pauvreté, bonheur et infortune, toute une humanité respectueuse, unie dans l'égalité du regret. La science ne se lassera point, messieurs, d'admirer dans le génie de Pasteur la force combinée d'une imagination créatrice et de la plus rigoureuse méthode expérimentale. Il a des inspirations subites qui le portent vers des découvertes inattendues; il a des instincts divinatoires qui le poussent dans des routes inexplorées; il a de ces fougues de pensée qui devancent la constatation des vérités, la préparent, la font plus rapide et plus sûre. Mais, lorsque s'est posé devant lui, dans une de ces illuminations géniales, un problème scientifique, il ne le tient pour résolu qu'après avoir questionné la nature, après avoir groupé ou éliminé les faits, après les avoir définitivement condamnés à répondre. Il se garde de faire peser sur la sincérité de ses observations le poids d'aucun préjugé philosophique. 'La méthode expérimentale,' proclamait-il dans son discours de réception à l'Académie, 'doit être dégagée de toute spéculation métaphysique,' et, après avoir revendiqué pour sa conscience le droit d'affirmer hautement ses convictions spiritualistes et religieuses, il réclamait, non moins énergiquement, pour la science toutes les prérogatives de la liberté. Et c'est effectivement la libre curiosité de son esprit chercheur, aiguillonnée par cette puissance inventrice et secondée par cette scrupuleuse recherche des réalités objectives, qui l'a guidé dans la longue et brillante évolution de ses travaux scientifiques.

* * * * * *

"C'était la reconnaissance du peuple, des pauvres, des humbles, qui montait déjà vers Pasteur vivant, telle qu'elle s'incline aujourd'hui, émue et attendrie, devant ses dépouilles mortelles, telle qu'elle survivra, éternelle et immuable, à travers les générations futures. 'Heureux,' disait Pasteur, 'heureux celui qui porte en lui un idéal et qui lui obéit.' Il a obéi toute sa vie à l'idéal le plus pur, à un idéal supérieur de science, de vertu, de charité. Toutes ses pensées et toutes ses actions se sont éclairées au reflet de cette lumière intérieure: il a été grand par le sentiment comme il a été grand par l'intelligence, et l'avenir le rangera dans la radieuse lignée des apôtres du bien et de la vérité. Adieu, cher et illustre maître! La science, que vous avez si grandement servie, la science immortelle et souveraine, par vous devenue plus souveraine encore, transmettra aux âges les plus lointains l'ineffaçable empreinte de votre génie. La France, que vous avez tant aimée, gardera fièrement comme un bien national, comme une consolation, comme une espérance, votre souvenir vénéré. L'humanité, que vous avez secourue, environnera votre gloire d'un culte unanime et impérissable, où elle verra se fondre toutes les rivalités, et où elle conservera, vivante et forte, la foi commune dans le progrès infini."

The troops defile before the *catafalque*, which the men salute, the President takes his departure, and then the coffin is carried under the porch of Notre Dame, where it is awaited by the Archpriest and clergy. Thus was brought to a conclusion a ceremony which will live long in the memory of all who were privileged to be present. Its imposing character is a proof that the public is not unmindful of the efforts patiently made in laboratories to combat disease; and it is an encouraging sign of the times that the remains of one who, by the creation of his method, has not only achieved great sanitary triumphs, but has paved the way for further and almost undreamed-of successes, should be conducted to his resting-place with honours hitherto reserved for great soldiers or statesmen.

Oct. 8th.

ROME.

(FROM OUR OWN CORRESPONDENT.)

The Congress of Internal Medicine.

THIS Italian counterpart to the British Medical Association, which was to have met here from the 14th to the 16th inst., has had to make an alteration in its programme and will not meet till the 22nd inst. No harm will be done by this postponement of a week. On the contrary, the President, his Excellency Dr. Guido Baccelli, will be in better condition for the duties than he would have been on the days originally appointed. He has been ill from the effects of over-work and, though now convalescent, will gain much by another six or seven days of much-needed repose. No other alteration will take place in the programme, the main features of which, as already stated, will be the report on Serotherapy, introduced by Professors Foà and Marigliano, and that on Decline (*rallentamento*) in Nutrition, introduced by Professors De Renzi and Reale. This Congress will differentiate itself from its predecessors by a modification on previous programmes. The "Congressisti" will, for the first time, be invited to hear in the great hospital of the Santo Spirito three clinical lectures from three of the most eminent teachers and consultants in the Italian schools—to wit, Professor Achille De Giovanni of the University of Padua, where he holds the chair of Clinical Medicine; Professor Pietro Grocco, who fills the corresponding post in the Istituto di Studi Superiori of Florence; and Dr. Alberto Riva, Professor of Clinical Medicine in the University of Parma. These highly accomplished and experienced physicians have consented with alacrity to initiate this novel feature in Italian Congresses of Internal Medicine and will have the gratification of finding themselves once more face to face with many old pupils or with colleagues from other provinces of Italy by whom they have been called in consultation.

Singular Case of Homicidal Mania.

The fiendish performances of "Jack the Ripper" have had their analogue in Italy, which country need be under no apprehension of losing its prominence in *reati di sangue*. As that murderer chose unfortunate women for his victims, so his Italian prototype selected little children as the objects of his lethal propensity. His *modus operandi* was strangulation, and, having perpetrated the deed, he buried the corpses secretly. For a considerable time he pursued his *métier* with impunity, until he had thus disposed of five "bambini" at least. Arrested and put upon his trial, he was condemned to twenty years of *casa di forze* (close confinement with hard labour), but, having just "served his time" (always in Italy considerably short of the nominal term), he has announced his intention of returning to the scene of his crimes, his native Incisa, in Piedmont. At this the families of that town and neighbourhood have risen in alarm, the mothers being especially vociferous in their protest. To prevent disturbances the local authorities have taken precautions, and a strong police force is already on the spot. But what surprised the medical world is the ill-judged action of the civil magistrates in allowing this murderer to be at large. A more typical case of homicidal mania, confirmed by every anthropometric and psychological test, has seldom come before the profession, and his having been confined in an ordinary prison and not in one specially appointed for criminal lunatics is cited as another illustration of that perverse adhesion to juridical prejudice which evokes such indignant remonstrances from Professor Lombroso and his school. According to a medical correspondent the man's head is of the most misshapen, cretinoid formation, while his whole symptomatology, during trial and in confinement, relegated him to the class called "degenerati" in Italian criminal anthropology. The popular excitement, this time at least, is too openly and passionately on the side of medico-psychology

Digitized by Google

to pass unnoticed by the authorities, civil and legal; and as I write provisions are on foot to prevent the man's reinstalling himself, unwatched or uncontrolled, in the neighbourhood he has saddened and sullied by his "slaughter of the innocents."

The Red Cross on the Red Sea.

In supplement to a previous reference to this medico-military enterprise I may add that there has set out for Massowah a new detachment of the Croce Rossa Italiana to reinforce the hospital of fifty beds now serving on the heights of Asmara. Some novel features have been introduced in the transport of this convoy. The small, but active and strong, Abyssinian mules have been turned to effective account, and also the hardy mountaineer population. The whole assortment of therapeutic and surgical appliances, linen, and such like is contained in impermeable sacks, while the materia medica and pharmaceutical gear, the *armamentarium chirurgicum*, and medical "comforts" are packed in small chests. The ambulance is further provided with a light, but strong and steady, operating-table, a tent, eight mountain *barelle* (transport seats), water barrels, &c. The Central Committee has prepared two such supplementary ambulances, aided by a handsome subvention from the Regional Committee of the Red Cross at Turin. One of these is, as I have said, on its way to the Erithrea (Red Sea Colony); the other remains here in reserve. The Sottotenente Medico (medical sub-lieutenant) of the Red Cross, Dr. Spinedi, is in charge of the convoy just started, with an efficient staff of *infermieri* (hospital attendants) under him.

Tourists and the Winter Season.

The Italian winter cities are preparing for the influx of the travelling world, the inhabitants of which are now showing an attention to "nettezza publica" (external tidiness) which they deny themselves until their English-speaking *clientèle* is expected. The great heat is now succeeded by delicious autumnal weather, and those who are fortunate enough to be now in Rome are revelling in the "Ottobrate" (October outings) so dear to native and foreigner alike and so brilliantly described in Cardinal Wiseman's "Fabiola." Rumour is busy with the names of distinguished visitors from the British Isles and has already made free with the plans of Her Most Gracious Majesty Queen Victoria. Naples, it says, is the probable scene of Her Majesty's vernal *villeggiatura*, and the public are gravely assured that the Queen will not be deterred from the Neapolitan Riviera by any fear of an eruption of Mount Vesuvius! The report, I need hardly say, is more than premature and seems to be little else than a revival of a similar one for which there was much more to be said just two years ago. Then there was no doubt that King Humbert had placed at Her Majesty's disposal the Palazza Reale at Capo di Monte, a magnificent mansion commanding an extensive view of Naples and surrounded by a park three miles in circumference, artistically laid out with delightful drives. The plan was that the Queen would first proceed to the Villa Fabricotti, near Florence, and after a sojourn there go by sea to Naples. This latter detail of her journey was *motivé* by the necessity of her avoiding Rome, where the difficulty felt by all Royal "arrivals" as to whether the Court of the Vatican or that of the Quirinal should receive their first visit is peculiarly real in Her Majesty's case—Leo XIII. being a personal friend of fifty years' standing, while Humbert I., though undoubtedly King of United Italy, is not acknowledged as such by His Holiness. No finer residence in Italy could be found for Her Majesty than Capo di Monte, its site between mountain and sea giving it a twofold advantage as to air, while in the first weeks of April, the time usually fixed for the Queen's sojourn, the easterly winds are followed by milder breezes, combining invigorating freshness with the warmth of a sub-tropical spring. But, as I have said, nothing is officially known as to Her Majesty's visiting Naples, any more than as to her coming to Florence, where the choice of a villa and the necessary preliminaries to a Royal sojourn are generally known months before they are put in requisition. In the case of Mr. Gladstone—another personage with whose winter movements report is busy—I believe the Riviera and Italy divide the preference of his advisers, it being still a question whether Cannes or Biarritz should come before Florence or Naples, or *vice versâ*. Next month, I understand, the final decision will be taken.

Oct. 6th.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The Municipal Elections.

THE strong anti-Jewish party in Vienna is jubilant in consequence of the elections having raised its leader, the famous Dr. Lueger, to the dignity of Mayor. The turmoil which has agitated a large part of the population of Vienna for the last two months has resulted in forty-six Liberals and ninety-two Antisemites being returned; there was no struggle for principles, but only for personal interests. Among those who have not been re-elected is that excellent hygienist, Professor Max Gruber, who was the representative of the Ninth District, the Vienna Quartier Latin. His opinion is that medicine ought to have no politics, and he therefore would not join either party. The municipality loses in him one of its best members and an authority on all questions of hygiene. Being a member of the Council of Hygiene his opinion on matters of public health is valued everywhere. Two physicians have been elected, Dr. Krenn and Dr. Rader, both of whom are uncompromising Antisemites; they will not, however, make up for the absence of Professor Gruber.

Charge against the Managers of a Hospital.

In Austria-Hungary there are a few hospitals under the care of the Brethren of Mercy (Barmherzige Brüder) which are conducted in an excellent manner, and in the Vienna hospital of this order the friars, who are duly qualified physicians, fulfil their difficult duties without deriving any personal advantage therefrom. The friars who conduct the hospital in Agram (Croatia) have, however, now been charged with neglect of cleanliness and with such parsimony that the patients do not receive a sufficiency of bread and meat. The linen is changed but twice a month, the mattresses, palliasses, and quilts are torn, and the kitchen utensils are in a bad condition, the glaze of the pans and the tinning of the copper vessels being worn off. There is so much overcrowding that the beds are placed in contact with each other and the patients cannot leave their beds without stepping across their neighbours'; some even lie on the floor or in the corridors. The nurses receive very low wages (12*s.* a month) and are thoroughly incompetent. The drinking-water is taken from the pipes in the waterclosets, and the hospital by no means satisfies modern requirements, the rooms being low, narrow, ill-lighted, and badly ventilated. Even the medicines are impure, and the patients' mixtures sometimes either consist only of water or else contain but a trifling quantity of the essential ingredient. This charge has not failed to cause a great sensation among the profession. It remains to be seen if it can be substantiated.

The Production of Antitoxin in Austria.

Up to July 1st camphorated serum has been supplied free of cost, its quantity amounting to 2130 bottles, containing 29,200 c.c. Since that time the gratis supply has been discontinued, and the price of a dose has been fixed at 2*s.* 5*d.*, each dose possessing a definite and experimentally ascertained curative power (100 units at least). The establishment is now capable of producing 1000 doses monthly. A dose of from 10 to 15 c.c. is sufficient in slight cases, but severe ones require a repetition of the treatment. The establishment directs the injection of the entire contents of a bottle, but when the serum is employed as a prophylactic from 2 c.c. to 3 c.c. are sufficient. The injection may be made on the anterior or inferior thoracic and abdominal regions or on the legs. The serum must not be exposed to light or heat.

Replantation and Transplantation of Teeth.

An interesting paper on this subject was read by Dr. Benedikt at a meeting of the Army Medical Staff at Budapest. He said that Ambrose Paré was the first who performed replantation of teeth, and was followed by Dupont and Pomaret, the latter of whom recorded a case where a tooth which had been extracted by mistake was replaced and eventually adhered. Weld has performed eighty replantations, among which two have failed, and he also proved by experiments on dogs that absolute integrity of the periosteum is one of the most important conditions of a permanent adhesion of the tooth. By replantation Dr. Benedikt means an operation by which a tooth is inserted into living tissue, with which it must enter into nutritive communication. He distinguishes between replantation and transplantation, the latter consisting in the transference of a

Digitized by Google

tooth from one person to another. In his experiments he appeals to Professor Scheff, who extracted teeth of dogs under anæsthetics and with antiseptic precautions, the teeth being placed in a solution of sublimate. The wound was then disinfected, the bleeding was arrested, the coagulum was removed from the alveolus, and the tooth which was to be replanted was pressed into the cavity. After two days a reddish border was to be seen, and the tooth could be moved backwards and forwards, but after two weeks it was securely fixed. According to Dr. Benedikt the indications for the above operation are loosening of the teeth, caries, and inflammation of the periosteum surrounding the root. A tooth which has been removed from its socket by mistake on the part of the dentist or by violence should be replanted. In the case of toothache from caries where it is impossible to apply any remedy to the painful place the tooth may be extracted, filled with stopping after removal, and then replaced. Dr. Benedikt proposes that the tooth should be carefully extracted, avoiding injury to the socket or the surrounding gum, for a fracture of the alveolus would render subsequent union impossible. The root is then to be trimmed as far as it is rough and eroded, and the tooth is to be replaced after the removal of the pulp and the disinfection of both tooth and alveolus with sublimate. The operation is followed by no great pain and by only a trifling inflammation of the gums.

A Plea for Venesection.

Venesection is not in favour in Austria. Practitioners of the modern school have never seen it performed during their student years, and there are only a few old surgeons who regard it as a powerful means of combating all feverish processes. It must, therefore, appear strange that one of the most eminent Austrian physicians, Professor Jaksch, advocated the use of venesection at a meeting of the Medical Society of Prague, pointing out that its great therapeutical value consists in the immediate decrease of the blood pressure and in the diminution of the number of substances which carry oxygen. It may be employed in pneumonia, but only as a last resource, when the system is overcharged with carbonic acid. From 200 c.c. to 300 c.c. of blood may be withdrawn, and then a sterilised solution of common salt such as is used in physiological experiments is to be injected subcutaneously. The success of this treatment is manifested by the disappearance of cyanosis. Phlebotomy may also be resorted to in uræmia, provided that the patient's blood is normal as regards red corpuscles. Cupping may be employed to relieve the symptoms of carbonic acid poisoning and the pain of pneumonia, being less injurious than narcotics. It will sometimes calm the severe pain of pleurisy, and has also been known to effect improvement in cases of cyanosis and dyspnœa caused by emphysema and heart disease.

Cholera in Galicia.

During the week between Sept. 24th and 30th 18 cases of cholera and 12 deaths have been reported, making a total of 94 cases with 57 deaths (60·6 per cent.) since the commencement of the outbreak.

NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Cholera among the Hawaiians.

THE present epidemic of cholera in the Sandwich Islands is traced to a vessel from Kobe, Japan. Five hundred and thirty-eight Chinese were landed on Quarantine Islet on Aug. 9th from the steamer *Belgic*. They were from Hong-Kong, but the vessel had taken freight at Kobe and Yokohama, the former being a place where much cholera existed. Three deaths occurred on the passage, the alleged causes being pneumonia and heart disease. After landing there were 4 cases resembling cholera, and 3 were fatal. Thorough disinfection and isolation were used, and, no more cases occurring, in due time the 535 Chinese were transported to their destination on country plantations. Meantime, the disease had appeared in aggravated form on shore. It has now been gradually increasing for more than two weeks, but solely among natives. It is stated that the probable reason is that, while others have been protected by the thorough disinfecting and general sanitation employed, the natives have, perhaps in every case, been infected by eating raw fish, crabs, or sea-moss from the harbour and shoals adjacent — food which other people dislike, but which Hawaiians crave for. In several cases the victims were known shortly before being attacked to have eaten heartily of raw fish. The first cases on shore appeared after a native feast where the above-named foods were supplied. It is quite probable that the crabs had penetrated graves of Chinese cholera victims in quarantine who has been buried in the shallow sands, and had afterwards crossed a half-mile of shoal water and been captured by fishing women and eaten raw. It is evident that the disease crossed that strait in some way to the nearest land. A majority of the victims are stricken down with great suddenness and live from three to eighteen hours. Seven-eighths of the cases are fatal. Up to Sept. 5th there have been 34 cases and 29 deaths in a population of about 5000 natives and 15,000 of other races within city limits. Why is the fatality of the attacks so extreme? In general, it may be replied, the Hawaiian dies easily. He has weak resisting power against disease; he succumbs where most men would recover. This is characteristic of the race, as abundant missionary and medical experience testifies. It is largely due to lack of mental courage; pain and violent sickness terrify him; he readily becomes hopeless and gives up; his friends and his medicine-man tell him that an evil god has grappled with his vitals; he feels the demon at work within him, and he yields to terror and dies. This is the history of a large proportion of deaths among the Hawaiians. Another reason for the great mortality of this disease is that in most of the cases no proper medical aid is received until too late. The natives will not report a case of cholera until the patient is beyond relief. Since a cholera hospital was opened and patients removed to it an absolute aversion has seized upon them. The majority of the natives have always been afraid to go to the Queen's Hospital, for they wholly distrust the white "doctor," because they have been taught belief in, and fear of, the minor gods and demons, and licensed medicine-men have held classes for instruction in incantations and demon lore. The fees of these medicine-men being at stake the sick have been taught to have nothing to do with the white "doctor." It is a popular belief that the medical men give poison to their patients in the hospital. Many are received into the hospital when it is too late to help them, and some are already dead before they are reached by the medical man.

Serum Treatment of Tuberculosis.

Mr. Paquin, Professor of Bacteriology in the Missouri State University, argues that as the horse is immune against tuberculosis, its blood serum ought to work beneficently in patients suffering from this disease. He has been using injections in fifty cases and thinks he has proved its value. He claims that the blood of the horse can be used direct, as it is naturally immune and needs no artificial immunisation. He injects the serum under the skin.

Enforcement of the American Sabbath.

The recent efforts of the police of New York to enforce the excise laws requiring the closing of liquor saloons on the Sabbath has aroused the opposition of the German population. New York has over 9000 licensed liquor saloons, and although the law requires that they shall not sell any intoxicating liquors on Sunday the police have been very lax in the enforcement of this provision. Under the reform administration the law has been rigidly enforced, followed by a great reduction of crime and an improvement in the public health. The agitation of the question of the justice of that feature of the excise law which closes the "poor man's club" on Sunday, as the advocates of the saloon call these low resorts, comes before a general election, and is, of course, eagerly seized upon by the politicians. The result of a popular vote can scarcely be doubted when the vast German and Irish voting population is considered, whose vote will be cast solidly for what they term "personal liberty." There is, however, a large reserved vote which rarely appears at popular elections, but which may be induced to come out to meet the emergency. The power that moves this conservative vote emanates from the pulpit and the religious press, both of which are entering into the canvass with unusual vigour, determined to preserve the "American Sabbath."

Sept. 26th.

Obituary.

SURGEON-GENERAL SIR THOMAS LONGMORE, KNT., C.B., F.R.C.S. ENG.

IN our last issue we only had time to make a brief announcement of the sudden death of Sir Thomas Longmore, the news of which reached us last week. It is now our task—painful yet full of interest—to lay before our readers the information which we have been able to gather concerning his life and work.

Sir Thomas Longmore was born at Southwark, in London, on Oct. 10th, 1816, so that at the time of his death he was within a few days of completing his seventy-ninth year. He was the eldest son of Mr. Thomas Longmore, a surgeon in the Royal Navy, who on retirement was appointed to the medical charge of Rockingham House, and of Maria, a daughter of Mr. John Elcum. He received his education at the Merchant Taylors' School and at Guy's Hospital, and in 1841 he was duly enrolled as a Member of the Royal College of Surgeons of England. At his hospital he soon made himself felt as an industrious student; he acted there as dresser to Mr. Bransby Cooper, and afterwards assisted him in his private practice and in writing Sir Astley Cooper's life. He also spent considerable time in arranging and cataloguing after the great surgeon's death the collection of specimens made by Sir Astley Cooper before the museum was purchased by the Royal College of Surgeons of England. On Feb. 3rd, 1843, he was gazetted to an assistant surgeoncy in the 19th Regiment of Foot. He joined the depôt at Dover, afterwards moving with it to Jersey and to Ireland. Early in 1845 he proceeded to the headquarters of the regiment in the Ionian Islands, and served with it there, in the West Indies, and in North America until its return to England in 1851. March 3rd, 1854, saw him gazetted as a regimental surgeon. He subsequently served with his regiment in the Light Division of the Eastern Army, and he was on duty from the date of its first taking the field, throughout the Crimean campaign of 1854-55, until the termination of the siege of Sebastopol, without being absent from his post for a single day. He, however, suffered not a little from the effects of frostbite during those never-to-be-forgotten winters, and to the day of his death carried the memory of hardships heroically and patiently borne, the results of which were, moreover, observable in his gait. He was present at the affair of Buljanac on Sept. 19th, at the battles of Alma and Inkerman, the battle of Balaklava, at the famous sortie on Oct. 26th, and at the assaults of the Redan on June 18th and Sept. 8th. For his services he received the medal with three clasps, the Turkish medal, and was made a Knight of the Fourth Class of the Legion of Honour. On the declaration of peace Mr. Longmore returned to England. He then very wisely improved his professional position by passing the examination for the diploma of the Fellowship of the Royal College of Surgeons of England. But he was not long allowed to remain in this country, for on the outbreak of the Sepoy Mutiny he was ordered with a detachment of his regiment to India, and during the years 1857, 1858, and 1859 served with the army in Bengal, at first as a regimental officer, but afterwards as Deputy-Inspector of Hospitals, the promotion to which rank, on Dec. 31st, 1858, was a further reward for his active services in the East. He thus attained administrative rank in less than sixteen years from the day on which he obtained his first commission. In January, 1859, he received the appointment of Sanitary Officer to the British Forces in Bengal, but in the following July, on the reduction of the establishment, he was ordered home and posted as Principal Medical Officer of the camp at Colchester.

During the Crimean War his skill as an operator had attracted considerable attention, and when, in 1860, Sidney Herbert founded the Medical School, for the better instruction of the medical officers of the army, the professorship of Military Surgery was offered to him and accepted on the advice and at the express desire of Dr. Alexander, the then Director-General. Endowed with excellent qualifications for the post, he filled it with much usefulness, dignity, and honour, and continued to hold it for nearly thirty-one years, until the termination of the summer session of 1891, when it became clear to him that he must seek the quiet and repose which age demands. After occupying the chair of Military Surgery for twelve years, on Oct. 19th, 1872, he was promoted to the rank of Inspector-(Surgeon) General, and in the same year he was appointed to be a member of the Committee on Field Hospital Equipment. Fourteen years later, on Oct. 10th, 1876, he was placed on the retired list, with permission to hold his chair of Military Surgery. On eight occasions he was called on to deliver the introductory addresses at the commencements of sessions of the School, and it fell to his lot to inaugurate the first sessions both at Chatham in October, 1860, and at Netley in May, 1863. In October, 1873, he took for his subject that of Hospital Arrangements in the Field, and the most effective means of affording surgical help to wounded soldiers on battlefields in European warfare. On a similar occasion, in April, 1878, he delivered an oration on the Existing State of our Naval, Indian, and Army Medical Services. In October, 1880, he dealt with the Antiseptic Treatment of Wounds in Military Practice in the Field, and at the opening of the winter session of 1886 he chose for the subject of his address Gentleness in Surgical Practice. His position as the acknowledged chief of the military surgeons of this country, at a time when the working of the Army Medical School and the organisation of our Medical Service were being studied by the chief Continental Governments, naturally brought his name frequently into great prominence and added not a few well-earned honours to the laurels which he had already won. Thus, from the date of his election in 1866, onward for many years he was "correspondant étranger" of the Société Impériale de Chirurgie de Paris; in 1877 he was elected "membre associé étranger" of the Société de Chirurgie de Paris; in 1884 he was made a corresponding member of the Academy of Medicine of France; and on March 27th, 1888, he was elected "associé étranger" of that institution. We have already mentioned that in 1857 he was made a Knight

SURGEON-GENERAL SIR T. LONGMORE, KNT., C.B.

Digitized by Google

of the Legion of Honour; in 1879, by the decree of the President of the Republic, he was promoted to the grade of "officier" of the Legion. On March 13th, 1867, he was nominated a Companion of the Military Division of the Order of the Bath, and on Sept. 16th of the following year was gazetted Honorary Surgeon to Her Majesty. On the death of Inspector-General Charles Whyte he was appointed (Jan. 3rd, 1881) to receive the "distinguished service reward" thereby rendered vacant. He received the honour of knighthood at Osborne in 1886. At the annual assembly of the Order of St. John of Jerusalem in 1874 he read a paper which was the starting-point of the St. John ambulance classes. He was among the earliest of those selected as associates of the Order, and he was a life member of the Ambulance Association, in the workings of which he ever took a lively interest. He was also a Fellow of the Royal Medical and Chirurgical Society and of other learned bodies, and was for many years consulting surgeon to the Southampton Free Eye and Ear Hospital.

Sir Thomas Longmore frequently had the honour of being sent as a representative of the British Government to foreign countries. As early as 1864 he was deputed to attend the Congress at Geneva since known as the "Geneva Convention of 1864." In 1867 he was sent to Paris to take part in the International Conferences of the Societies for Aid to Wounded Soldiers in time of War. In 1869 he was at Berlin, as the British Government delegate, to take part in an International Conference on Aid to Sick and Wounded in War. In 1873 he was sent by the War Secretary to Vienna to report on the field hospital equipment collected at the "Sanitäts-Pavillon" of the World-Exhibition in that city. In 1876, at Brussels, he was president of a committee ordered to report on the appliances for aid to sick and wounded in war exhibited in the Sanitary Exhibition there. At Paris, in 1878, he represented the Government in an International Congress to consider the Medical Arrangements of Armies in the Field. At the International Medical Congress held in London in 1881 he was President of the Section of Military Surgery and Medicine, and in his address gave a sketch of the existing arrangements for ensuring systematic help and skilled attention to the wounded in case of England becoming involved in war (published in the Transactions of the Congress and in THE LANCET of Aug. 6th, 1881). In September, 1884, he again represented the Government at Geneva at the Conference of the Societies for Aid to Sick and Wounded in War; and in the autumn of 1887 he was sent to Carlsruhe to be present at the International Red Cross meeting in that city. In the June of the latter year the annual meeting of the Southern Branch of the British Medical Association was held at Netley, and Sir Thomas Longmore, as the President, delivered the annual address. In 1888 he was invited to act at Antwerp as British representative and member of the international jury for assessing the prizes offered by the Empress Augusta of Germany for the best forms for a movable hut-hospital. His report on the exhibition and the proceedings of the jury are printed in Vol. XXVI. of the Army Medical Reports. In October, 1889, he was sent by the Secretary of State for War to Paris to take part in the fourth session of the French Surgical Congress; he was elected one of the vice-presidents, and subsequently (1890) published a report on the proceedings, with observations on the Military Medical Schools of France. Of these conferences his reports may be found in the Army Medical Department Reports and in the special Transactions of the Congresses. The work which he did so well in the Army Medical School is shadowed forth in his writings. Although not a brilliant or voluble lecturer, he was most painstaking, precise, and conscientious. Those who listened to his discourses during the many years in which he held his chair, carried away with them the impression of the thoroughness with which his lectures were prepared and of the pains and trouble he took to make even the smallest point intelligible to them. When delivering his last address on July 17th, 1891, after announcing his coming retirement in terms of characteristic modesty and expressing that high sense of public duty which marked his whole career, he epitomised the changes and vicissitudes incidental to a growing and developing Service. No man could speak on such a subject with greater authority, for his one aim in life was to be, as far as may be, and not merely to be considered, a perfect soldier-surgeon. Entering the army as a regimental officer, he saw the regimental system abolished, the germ of a new, separate, and independent medical department planted in its stead, and he long and carefully watched its growth and development. We can echo the remark which Dr. R. Farquharson made (speaking of Sir Thomas Longmore's retirement, after distributing the prizes at the termination of the summer session of the Army Medical School, 1891), when addressing the young officers, that "they would know better some day than they did now that the progress of military surgery for the last thirty years was more intimately associated with the name of Longmore than with any other."

The career of Sir Thomas Longmore as a writer commenced about the year 1859, when he published a "Synopsis of Sixteen Cases of Heat Apoplexy" which occurred in Her Majesty's 19th Regiment at Barrackpore; it appeared in THE LANCET of March 26th of that year. He wrote a description of two additional cases in the sixth volume of the "Indian Annals of Medical Science." These papers were followed by a "Report on Gunshot and Sabre Wounds of Invalids sent to Fort Pitt during the years 1860 and 1861," which consisted of thirty pages and which he extracted from the Statistical, Sanitary, and Medical reports of the Army Medical Department; it was issued in the October of 1863. His first important literary work, however, was "The Illustrated Optical Manual," published in 1863, the earlier editions of which were intended exclusively for military practice. This manual reached a fourth edition in 1888, when it was issued as a text-book for civil as well as for military surgeons. Following these efforts there came from his pen these papers and books: "Remarks on the recently proposed American Plan of treating Gunshot Wounds of the Chest by Hermetically Sealing" (THE LANCET, Jan. 2nd, 1864); "A Note on some of the Injuries sustained by the late President of the United States" (President Lincoln) in THE LANCET of June 17th, 1865; a Catalogue of the Museum of Military Surgery at Netley (1867); a paper on "Amputation at the Knee-joint in Military Practice" (*Brit. Med. Jour.*, Jan. 5th, 1867); "A Treatise on the Transport of Sick and Wounded Troops" (1869), which he dedicated to his esteemed colleagues at Netley, to whose affectionate care he was so greatly indebted for recovery from a severe illness, and which was rightly described at the time of publication as "the most careful and thorough work on the transport of sick and wounded troops which has been published in any country"—a second edition of this work was brought out in the year 1893, edited by Surgeon-Captain W. A. Morris; "Remarks on the Instruments designed for Exploring Gunshot Wounds with a view to detect bullets or other foreign bodies suspected to be lodged in them" (*Brit. Med. Jour.*, Dec. 23rd and 30th, 1871); "Ambulances and Ambulance Service" (1875); "The Appliances for Aid to the Sick and Wounded in War, exhibited at Brussels in 1876"; "Instruction on the Examination of Recruits" (1882); "The Sanitary Contrasts of the British and French Armies during the Crimean War," published in 1883, in which he brought to notice the special circumstances which exercised so disastrous an influence on our army in the Crimea, and the measures which were adopted to restore its health; "On Field Dressings for Use in Time of War" (1887); an essay "On Gunshot Injuries" in the successive editions of "Holmes' System of Surgery"—in the third edition (1883) it extended to rather more than 100 pages (this essay had been previously reprinted both in the United and Confederate States, and was officially distributed during the Civil War); "The New Military Weapons and Explosives" (*Brit. Med. Jour.*, March 5th, 1892), being some observations which he forwarded to Geneva in support of a proposal to consider, at the approaching International Congress of Red Cross Societies at Rome, whether any modifications of existing field hospital arrangements were required owing to the general adoption of the new weapons and explosives in armies; and a biographical study of Richard Wiseman, Sergeant-Surgeon to Charles II., published in 1891. His *magnum opus* was entitled "Gunshot Injuries: their History, Characteristic Features, Complications, and General Treatment," the first edition of which he produced in 1877. It is the book which, next to Parkes' "Manual of Hygiene," is best known to the officers of the military medical services. A second edition, necessitated by the changes in the firearms and projectiles of all the leading armies, has just been issued from the press. It consists of nearly 800 pages, and occupied his attention to within a few weeks of his death. Sir Thomas Longmore has in this new edition endeavoured to bring his work up to date; on it he laboured but too well and

Digitized by Google

too continuously for his own welfare; we know that he spared neither time nor trouble on the endeavour, and we feel sure it will be widely appreciated. We have already briefly stated that Sir Thomas Longmore was a member of several learned societies. As a Fellow of the Royal Medical and Chirurgical Society he was a frequent attendant at the meetings, and read the following papers, which can be found in the Transactions: "Remarks on Two Cases of Kelis" (1863); "On the Classification and Tabulation of Injuries and Surgical Operations in Time of War" (1871); and "Remarks upon Osteo-myelitis consequent on Gunshot Wounds of the Upper and Lower Extremities, and especially upon the treatment of stumps affected with Osteo-myelitis after amputation necessitated by such injuries" (1865). To the Army Medical Department Reports he was also a frequent contributor. Among his papers may be mentioned "Remarks on some of the Prussian Arrangements for the Transport of Wounded in Time of War" (1870); the report of a case of "Transfixion of the Right Side of the Chest and Right Lung by a Lance, with Recovery" (1871); the Reports on Invalids admitted into the Royal Victoria Hospital, Netley, for wounds and injuries received in New Zealand and in Egypt during the campaigns of 1865 and 1882 (Army Medical Department Reports, 1866, 1883); a Description of a preparation of the upper part of a femur after gunshot fracture, sent to Netley for preservation in the Museum (1884); and a "Report on the Competitive Exhibition of Movable Hut-hospitals at Antwerp in September, 1885." In these reports also appeared the introductory address he delivered at Fort Pitt on the opening of the Army Medical School; a Lecture on the relations of the Army Medical Department and its officers to other departments of the army; Notes on the examination of visual fitness of recruits; a Summary of the numbers, classes, and results of the gunshot and sabre wounds inflicted during the Mutiny; Remarks on hand-wheel litters; and a description of the water-colour drawings executed by Sir Charles Bell illustrative of wounds received at Waterloo. Though his writings are thus shown to be almost exclusively confined to military and medical professional subjects, yet in his account of Wiseman he has given us a glimpse of his keen appreciation of the work of the historian and biographer, and allowed the outside world to know something of that inner nature, so well known to his friends, which was devoted to a wider literature.

On Feb. 11th, 1862, he married at East Claydon, Bucks, Mary Rosalie Helen, second daughter of the late Captain W. S. Moorsom, of the 52nd Regiment, by whom he had issue four sons and three daughters. It is not for us here to say much of his private life or of the charm of the home circle, of which he was ever the centre and figurehead: we have been writing of the man as we knew him in his official capacity. As, however, we have been admitted to see something of his home life, and have enjoyed the privilege of spending pleasant hours with him since his retirement, we may, perhaps, be permitted to touch on the singular charm of character and mind which he possessed and which endeared him to all hearts. Many of his younger friends were wont to wend their steps towards his home when in want of human sympathy and of the sound and ripe advice which were ever at their service. Passing from the environment of our age—of rush and callous cynicism—we have felt, when nearing the threshold of "The Paddock," as if we were breathing a purer air and entering an area of calm judgment and repose. Not a few of us have, we think, returned from visiting him braced with a better courage to fight life's battle, and some, when passing down the drive from his home, carried to higher realms of thought, have heard an echo of the late Laureate's lyre—

> "A second voice was at mine ear,
> A little whisper silver-clear,
> A murmur, 'Be of better cheer.'"

In the drawing-room of this home, of which he was the light and life for over twenty-five years, hangs the replica of the portrait the original of which, painted by George Reid of Edinburgh and exhibited at the Royal Academy in 1887, now occupies an honourable position in the ante-room of the officers' mess at Netley. It was presented to the Army Medical Department by Sir Thomas Longmore's comrades of the Military Medical Departments as a testimonial in recognition of his great services. Both the portrait and the replica, which latter was presented to Lady Longmore, are excellent likenesses. He is represented, in undress uniform, in the act of delivering a lecture; the artist has been singularly happy in catching that expression of earnest thoroughness which was usual to him on such occasions. His death was terribly sudden, though to those who knew him well it did not come as a surprise, for during the last few years he had many times suffered from attacks of cardiac weakness associated with faintness and other warning signs. On the morning of Monday, Sept. 30th, he was apparently in his usual health, and at a quarter past seven o'clock said farewell to his son-in-law who had been staying with him; before 8 o'clock he was no more. Though his call came thus suddenly his friends well knew that he was ready, and that, inspired with a holier and sublimer faith than the great Roman orator possessed, he could with a more joyful anticipation exclaim: "O præclarum diem, cum ad illum divinum animarum concilium cœtumque proficisci." From Swanage, Dorset, where, as had been his custom for many years, he had been spending a few weeks, his body, enclosed in a coffin of unpolished oak, was brought to Hamble, the village where he resided during his early Netley days, on the evening of Oct. 2nd, and at three o'clock on the following afternoon it was consigned to a grave on the north side of the churchyard, in the presence of his widow and family and a large gathering of friends. Among the latter were included the present staff of the Army Medical School and the military medical staff of the Royal Victoria Hospital, headed by Sir William Mackinnon, K.C.B., the Director-General. His old friend, the Rev. T. L. O. Davies, Vicar of Woolston, and the Rev. J. J. Curling, Vicar of Hamble, read the impressive service.

Our duty is all but finished; we have endeavoured to tell of the work of Sir Thomas Longmore, of the work of a man who ever trod strictly in the straight path, who did justice, and loved mercy. Of him we may truly say that no man rendered greater services to his Department, nor strove more in his generation to advance its interests, to promote scientific progress, and to raise to a high standard professional military education. In conclusion, we feel we cannot do better than quote the words which Sir William Mackinnon made use of at the meeting of the Senate of the Army Medical School, held in July, 1891, when giving expression to the unanimous feeling of regret felt on Sir Thomas Longmore's retirement from public life; he said that Sir Thomas Longmore "had not only raised the reputation of the Army Medical School as well as the Medical Service of the army generally by his great works on military surgery and ambulance transport and by his many admirable works and reports, but had achieved through the medium of these a reputation throughout Europe and America which reflected infinite credit upon the Service of which he was so bright an ornament."

WILLIAM HENRY BELLOT, M.D. ERLANGEN, L.R.C.P. EDIN., F.R.C.S. ENG.

WE regret to have to record the decease of a venerable and highly respected member of our profession, Dr. Bellot of Leamington, who passed away on Sept. 24th at the advanced age of eighty-four years. He was the son of a Manchester surgeon and became a Licentiate of the Society of Apothecaries in 1833. In the following year the Royal College of Surgeons of England admitted him as a Member and conferred the Fellowship on him in 1852. For many years he practised in Stockport in association with his uncle, Mr. Bellot, and married the daughter of Mr. Killer, an old-established practitioner in the town. In addition to many other public appointments he was staff surgeon to the Cheshire militia and honorary surgeon to the Stockport Infirmary. In 1860 he took the diploma of L.R.C.P. Edin., and graduated as M.D. of the University of Erlangen in 1862. About thirty years ago Dr. Bellot took up his residence in Leamington, where he gave much of his attention to the affairs of the public institutions of the town, and up to the time of his death was on the committee of the Warneford Hospital. He has left a widow and family.

A MEETING of the South-Western Division of the Medico-Psychological Association will be held at Wonford House, Exeter, on Tuesday, Oct. 15th. Dr. Deas will provide light luncheon between 1.30 and 2.30 P.M. Wonford House is fifteen minutes' drive from Queen-street Station, and twenty minutes' from St. David's. Dr. Deas will open a discussion on the Uses and Limitation of Mechanical Restraint as a Means of Treatment; Dr. Mac-Donald will read a paper on Nursing; and Dr. Morton will read Notes on three cases of Spontaneous Gangrene.

Medical News.

UNIVERSITY OF CAMBRIDGE: EXAMINATION IN SANITARY SCIENCE.—The following candidates have satisfied the examiners in both parts of the examination:—

Robert Frederick Carse, Christopher Childs, Thomas Dunlop, John Galletly, James John Gorham, Charles Robert Mortimer Green, Patrick Gill Griffith, Charles Williams Hayward, Ernest Hill, Kate Marion Hunter, Arthur Jervis, David Clark Muir, George Newman, William James Potts, John Thomson Prangnell, and Malcolm Alexander McIntyre Sinclair.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.—The following gentlemen passed the Second Examination of the Board in the subjects indicated on Monday, the 7th inst.:—

Anatomy and Physiology.—Alfred Holroyd, Yorkshire College, Leeds; Guy Harle Irvine, Frederick Arthur Coates, Edgar Steele Edwards, and James Williamson Wallace, University College, Bristol; Saville Bentley, Firth College, Sheffield; Arthur Myddleton Dodd and Alfred Johnson, University College, Liverpool; Frank Edward Wayte and William Taylor Jackson, Owens College, Manchester; James Henry Mort, Cambridge University and Owens College, Manchester; Geoffrey Orr Fern Sealy, Grant Medical College, Bombay; Edward Hugh Musgrove, University College of South Wales, Cardiff; Joseph Longheed Baskin, Queen's College, Cork; and Willoughby Arthur Blackstone, University College, London.

Anatomy only.—George Whittenburg White, Firth College, Sheffield; Edgar Ashby, Guy's Hospital; and George Beley, St. Thomas's Hospital.

Physiology only.—William Stanley Boothman, Owens College, Manchester; George Lionel Wright, University College, Bristol; Charles Braginton Salway, St. Thomas's Hospital; Arthur Bradshaw Passmore, Guy's Hospital and Durham University; Edward Thomas McDonnell, Queen's College, Belfast, and Mr. Cooke's School of Anatomy and Physiology; and Martin Clover, University College, London.

Seventeen gentlemen were referred in both subjects, four in Anatomy only, and one in Physiology only.

Tuesday, the 8th inst.:—

Anatomy and Physiology.—Cecil Francis Watson, Harry Stanley Turner, Robert John Pritchard, and Edward Cecil Davies, Guy's Hospital; Francis Lionel Rae, Cambridge University and Guy's Hospital; Henry Herbert Elworthy and Charles Stanley Cato, Westminster Hospital; John Maltby Edwards, Charing-cross Hospital and Mr. Cooke's School of Anatomy and Physiology; Horace Sampson Roch, King's College Hospital; Charles Edward Evans, University College, London; Samuel Hey, Cambridge University and St. Bartholomew's Hospital; William Inglis Bradley, McGill College, Montreal, Canada; George Young, London Hospital and Trinity College, Dublin; Alfred Reginald Key, Isaac Llywelyn Morris, and Francis Graham Richards, St. Bartholomew's Hospital.

Anatomy only.—John Edmund Francis and John William Cheese, University College, London.

Physiology only.—Guy Berners Nicholson, Cambridge University and St. Bartholomew's Hospital; Edwin Fryer, Guy's Hospital and Mr. Cooke's School of Anatomy and Physiology.

Sixteen gentlemen were referred in both subjects, two in Anatomy only, and two in Physiology only.

SOCIETY OF APOTHECARIES OF LONDON.—The following candidates passed in the under-mentioned subjects (September, 1895):—

Surgery.—Butcher, F., Royal Free Hospital; Garrow, A. E., McGill University; Jones, R., St. Mary's Hospital; Preston, C. C., Manchester; Renshaw, C. A. K., Cambridge and Manchester.

Medicine, Forensic Medicine, and Midwifery.—Breton, L. M., St. Thomas's Hospital; Butcher, F., Royal Free Hospital; Cryer, J., Manchester; Garrow, A. E., McGill University; Old, J. E. S., London Hospital; von Humpe, E. T. V., Royal Free Hospital.

Medicine and Forensic Medicine.—Abbott, T. B., Leeds; Downes, G., Dublin.

Medicine.—Sims, E. E., Leeds and Glasgow.

Forensic Medicine.—Grace, A. H., Bristol; Hilton, A., Manchester; Holst, M. K. S., Royal Free Hospital; Young, T. W. H., Toronto.

Midwifery.—Goulden, R., Manchester; Wallis, P. E., University College.

To Messrs. Abbott, Breton, Butcher, Cryer, Downes, Garrow, Old, and Sims was granted the diploma of the Society entitling them to practise medicine, surgery, and midwifery.

Primary Examination. Part II.

Anatomy and Physiology.—J. W. Cheese, University College; L. D. B. Cogan, Guy's Hospital; G. S. Foulds, Manchester and Edinburgh; E. Fryer, Guy's Hospital; C. E. Hogan, St. Bartholomew's Hospital; D. V. Lowndes, London Hospital; B. S. O. Maunsell, St. Bartholomew's Hospital; H. E. Miller, Guy's Hospital; and C. E. White, Edinburgh.

Anatomy.—S. E. Bhagtani, King's College Hospital; H. Charles, Middlesex Hospital; J. C. S. Dunn, St. Bartholomew's Hospital; G. W. Dutton, Middlesex Hospital; J. Elul, Edinburgh; B. Hogan, London Hospital; A. E. Hoare, St. Thomas's Hospital; R. O. Jones, Guy's Hospital; E. F. Lamport, Royal Free Hospital; and H. W. B. Walling, Guy's Hospital.

Physiology.—F. G. Aldrich, Charing-cross Hospital; H. J. de Saram, Middlesex Hospital; A. H. FitzGibbon, St. Bartholomew's Hospital; W. M. Hocken, Liverpool and Edinburgh; H. G. Lewer, Edinburgh; E. P. Marett, St. Thomas's Hospital; W. P. E. Newth, St. Thomas's Hospital; and J. Scarr, Manchester.

Biology.—E. Yoxall, Birmingham.

Chemistry.—R. Brookes, Westminster Hospital; C. H. Thomas, London Hospital; and A. H. Wilson, Birmingham.

Materia Medica and Pharmacy.—F. E. T. Evans, Royal Free Hospital and E. C. Scarlett, Royal Free Hospital.

Materia Medica.—H. Greenwood, London Hospital.

THE LONDON HOSPITAL MEDICAL SCHOOL.—The Price Scholarship in Science, value £120, has been gained by Mr. H. Balean; Science Scholarships of £60 and £35 respectively by Mr. O. Eichholz and Mr. A. B. Soltau. Price Scholarship in Anatomy and Physiology for university students has been awarded to Mr. R. C. Wall and Mr. J. H. Evans jointly.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—The annual meeting of this society was held at the Miller Hospital, Greenwich, on Oct. 4th, when the following officers were appointed for the ensuing year:—President: Ernest Clarke, M.D., B.S. Lond., F.R.C.S. Vice-Presidents: Peter Cooper, M.R.C.S., L.R.C.P.; and Frank Tayler, B.A., M.B. Lond. Council: A. Stewart Brown, F.R.C.S. Edin.; Morgan Dockrell, M.A., B.Ch., M.D. Dub.; George Herschell, M.D. Lond.; Arbuthnot Lane, M.S. Lond., F.R.C.S.; Clarke Morris, M.R.C.S.; C. J. Parke, M.R.C.S.; and Septimus Sunderland, M.D. Brux. Treasurer: Prior Purvis, M.D. Lond. Secretary: E. H. Ezard, M.D., C.M., D.Sc. Edin. Librarian: J. P. Henry, B.A., M.D., B.Ch. Dub. The Purvis Oration was delivered by Professor Curnow, M.D., who chose for his subject, Medical Examinations and Medical Education.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Thursday, Oct. 3rd, the President (Dr. Uhthoff) in the chair. Messrs. John Bradbury Winter and John Francis Atkins were elected members of the society. Dr. A. J. Richardson showed a child from the Sussex County Hospital suffering from infantile palsy in both legs with double talipes equino-varus. Dr. Richardson also showed photographs of a case of Sciopody in a girl aged ten, who was under his care. Mr. Sanderson showed a patient for whom nine months ago he had removed the breast for scirrhus, as well as the lymphatics of the axilla and of the posterior triangle, and he strongly recommended this extension of the operation in all cases. Dr. Uhthoff gave an account of a very rapid case of diabetes in a girl aged seventeen, who passed quickly into diabetic coma, fatal in six hours. Dr. Maynard read notes of an unusual case of intestinal obstruction in which dilatation of the stomach had existed for a long time. Colotomy had been followed by complete relief from all the symptoms of dilatation.

THE CHURCH SOCIETY FOR THE PROMOTION OF KINDNESS TO ANIMALS AND THE CHURCH SANITARY ASSOCIATION.—At the annual meetings of the Church Society for the Promotion of Kindness to Animals and the Church Sanitary Association, which were held jointly in the Church House, Westminster, under the presidency of the Dean of Rochester, Dr. Sykes, medical officer of health for St. Pancras, read a paper on Public Slaughter-houses and the Proper Inspection of Meat. In the course of the proceedings it was mentioned that the societies had memorialised the London County Council, the Board of Agriculture, and the Local Government Board for amended legislation in respect of public slaughter-houses. Dr. Norman Kerr said that their object was to carry to every parsonage in the land the conviction that it was the duty of the clergy to make use of the Church's machinery in every parish to secure improved sanitation and the greatest possible immunity from infectious disease. The Rev. Septimus Buss, Vicar of Shoreditch, remarked that the question of the clergy dealing with the public health had been a matter of discussion. The opinion of the Church Sanitary Association was that, while it was the first duty of the clergy to press upon the people the acceptance of the Gospel, it was right that they should also deal with those things which concern the welfare of the body. The Dean of Rochester, in the course of a long address, described a visit which he had recently made to an establishment in Chicago, the largest of its kind in existence, where 8000 pigs and 3000 cattle were slaughtered daily. Everything was done as humanely as possible, and he did not believe that any more pain was inflicted than was absolutely necessary. In his concluding remarks Dean Hole strongly advocated the adoption of smoke-consuming furnaces, and complained that Rochester, which twenty years ago was one of the prettiest cities in the kingdom, now suffered very much from the unwholesome and offensive emanations of the cement factories.

BRISTOL UNIVERSITY COLLEGE.—The winter session commenced on Oct. 2nd, when the opening address was delivered by Sir C. M. Kennedy, K.C.M.G., C.B., late of the Foreign Office and Vice-President of the Society of Arts of London. Sir C. Kennedy has joined the staff of the College as lecturer upon international law, and his address was entitled "Diplomacy and International Law."

FOOTBALL CASUALTIES.—On Saturday last one of the backs in the Grantham Rovers' team, while playing a match at Grantham between the Grantham Rovers and Wellingborough teams, fractured his right leg below the knee, and was conveyed to the hospital. On the same day a young man, during a game at Farnworth, sustained injuries to the abdomen, from which he died on Tuesday last.

MRS. SAXTON, of the Elms, Shrewsbury, has given a sum of money to the Salop Infirmary from the funds of the Gwyn Trust. The interest of this money is to be devoted to the maintenance in perpetuity of two beds in the children's ward, over each of which an inscription will be placed stating the endowment to have been furnished by Mrs. Saxton in memory of her parents.

THE SIXTH INTERNATIONAL CONGRESS OF OTOLOGY.—The Sixth International Congress of Otology will meet in 1899, as already stated, in London, and its organising committee is thus constituted: Dr. C. A. Ballance, Dr. A. E. Cumberbatch, Sir W. Dalby, Mr. G. P. Field, Dr. J. Dundas Grant, Mr. T. Mark Hovell, Dr. U. Pritchard (President), Dr. W. Laidlaw Purves, and Dr. St. Clair Thomson, all of London; Mr. Cresswell Baber, Brighton; Dr. T. Barr, Glasgow; Dr. A. Bronner, Bradford; Dr. J. W. Browne, Belfast; Dr. C. E. Fitzgerald, Dublin; Dr. P. McBride, Edinburgh; Dr. F. M. Pierce, Manchester; and Mr. G. Stone, Liverpool.

THE GUILD OF ST. LUKE, EVANGELIST AND PHYSICIAN.—The thirty-first anniversary of this Guild will be celebrated next week. On the Feast of St. Luke Evensong will be sung at St. Paul's Cathedral, when the Bishop of St. Andrews will be the preacher. The music will be rendered by the London Gregorian Choral Association, and the offerings will be for the expenses of the services and the Medical Missionary Fund. On the following day there will be a corporate Communion of the Guild at the Church of St. Thomas, Regent-street, at 8 A.M., and there will be celebrations for the intention of the Guild in some 600 churches throughout England and Wales, Scotland, and America. On Saturday, Oct. 19th, the annual general chapter will be held at the Holborn Restaurant at 6 P.M., when the report of the council will be presented, the Provost's address delivered, and the officers elected for the ensuing year.

DIPHTHERIA IN LONDON.—Last week diphtheria in London was not quite so fatal in form as in the week preceding, so far as London proper was concerned at all events; but it is now exhibiting a phase which is by no means of a satisfactory character, inasmuch as the disease is assuming a fatal tendency in the suburbs above its recent records. In the West Ham registration district it has for a long time shown a disposition to remain epidemic, and during last week it was widespread in East and West Ham, not being confined to Plaistow, as has been its wont for the most part. The deaths in the whole district last week numbered 10; and in addition to these there were 4 registered in the northern union of Edmonton, some of them in the suburb of Hornsey, and others as far out as Cheshunt; while on the west the suburban locality of Willesden was fatally invaded, 4 deaths being recorded there in the week. In all there were 31 registered deaths from the disease in the outer ring of the metropolis, only 13 short of the number for the whole county of London. The 44 registered deaths in the county were a fall from 56, and only 2 in excess of the corrected decennial average for the corresponding week of the years 1885-94. They all occurred in young persons under the age of twenty years, and 5 belonged to St. Pancras, 4 to Hackney, and 3 each to Kensington, Bethnal-green, Limehouse, Poplar, and Greenwich sanitary areas. The admitted cases to hospital were 90 in number, a smaller total than in many weeks past, former recent totals being 105, 114, and 114. The patients remaining in hospital—namely, 672—were much the same as for some weeks successively, but the attacks show no such diminution as the admissions and deaths seemed to warrant last week.

SOCIETY OF ANÆSTHETISTS.—The third annual meeting of this society will be held at Limmer's Hotel, Conduit-street, W., on Thursday next, Oct. 17th, at 7 P.M., to receive the reports of the council and treasurer and to elect the officers and council for the ensuing year.

ROYAL BRITISH NURSES' ASSOCIATION.—A donation of £100 has been made by an anonymous donor to the funds of this association. We are asked to state that the gift is most gratefully acknowledged by the treasurer on behalf of Her Royal Highness the President and the Executive Committee.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—*University Scholarships:* R. R. Wade, B.A., Exeter College, Oxford, £52 10*s.*; G. S. Keeling, B.A., Caius College, Cambridge, £52 10*s.* *Natural Science Scholarships:* W. H. Willcox, £105; H. Lovell-Keays, £52 10*s.*; E. W. Holyoak, £52 10*s.*; A. F. Hayden, £52 10*s.*

Lockwood: The Operation for the Radical Cure of Hydrocele by Excision of the Sac (illustrated with a series of cases).

TUESDAY.—PATHOLOGICAL SOCIETY OF LONDON.—Papers:—Dr. Ord and Dr. Plowright: Spontaneous Disruption of Calculi.—Mr. D'Arcy Power: Primary Sarcoma of Vagina of Child.—Dr. Wm. Collier: Multiple Polypi of Stomach and Intestines.—Mr. Jackson Clarke: Tertiary Syphilitic Lesions in Lymphatic Glands.—Dr. Herbert Snow: The Non-existence of Round-celled Sarcoma as a Distinct Class of New Growth. Card Specimens:—Dr. Kanthack: (1) Dissecting Aneurysm; (2) Cylindroma of Large Intestine; (3) Diffuse Primary Sarcoma of Liver.—Mr. Targett: Old Injury of Humerus from an Egyptian Mummy.

WEDNESDAY.—NORTH-WEST LONDON CLINICAL SOCIETY.—8.30 P.M. Clinical Meeting.

ROYAL MICROSCOPICAL SOCIETY (20, Hanover-sq., W.).—8 P.M. Prof. J. B. Farmer: On the Division of the Chromosomes in the First Mitosis of the Pollen-Mother-Cell of Lilium.—Mr. G. Massel: New and Critical Fungi.—Mr. F. J. Reid: A Fluorescent Bacillus.

THURSDAY.—OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM (11, Chandos-street, Cavendish-square, W.).—Card Specimens at 8 P.M.:—Mr. Ernest Clarke: (1) Rare Form of Nystagmus; (2) Orbital Tumour.—Dr. Mott and Mr. Treacher Collins: Case of Exophthalmos associated with Trigeminal Hemianalgesia.—Mr. Lawford: Retinitis Circinata. 8.30 P.M. Introductory Address by the President. Papers:—Mr. Treacher Collins: Four cases of Bilateral Glioma of the Retina cured by Enucleation of both Eyes.—Mr. Devereux Marshall: Detachment of the Choroid.—Mr. Kenneth Scott: Keratitis occurring in Leprosy.

HARVEIAN SOCIETY.—8.30 P.M. Dr. E. Symes Thompson: On the Climate of Egypt.

FRIDAY.—BRITISH LARYNGOLOGICAL AND RHINOLOGICAL ASSOCIATION. Cases by Dr. Geo. Stoker, Dr. Ed. Law, Dr. Wm. Hill, and Dr. Dundas Grant. Paper by Mr. R. Lake on a case of Keratosis Obturans. Discussion on the Treatment of Ménière's Symptoms. President's Inaugural Address.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MONDAY.—LONDON POST-GRADUATE COURSE.—London Throat Hospital, Great Portland-street, W., 8 P.M., Dr. E. Law: Examination of the Throat and Nose

TUESDAY.—LONDON POST-GRADUATE COURSE.—Bethlem Hospital, 2 P.M., Dr. Craig: Melancholia.

WEDNESDAY.—NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC (Bloomsbury).—3 P.M. Lecture by Dr. Beevor.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester-square, W.C.).—5 P.M. Dr. Morgan Dockrell: Eczema.

WEST LONDON POST-GRADUATE COURSE (West London Hospital, W.).—5 P.M. Dr. Abraham: Dermatological Cases.

THURSDAY.—LONDON POST-GRADUATE COURSE.—Hospital for Sick Children, Gt. Ormond-st., 3.30 P.M., Mr. C. A. Ballance: Selected Surgical Cases—National Hospital for the Paralysed, Bloomsbury, 2 P.M., Dr. Ormerod: Ataxia.—Central London Sick Asylum, Cleveland-st., W., 5.30 P.M., Dr. Patrick Manson: Sprue.

FRIDAY.—LONDON POST-GRADUATE COURSE.—Bacteriological Laboratory, King's College, 3 to 5 P.M., Prof. Crookshank: Examination of Air, Soil, and Water.

SATURDAY.—LONDON POST-GRADUATE COURSE.—Bethlem Hospital, 11 A.M., Dr. Percy Smith: Hypochondriasis.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN (Leicester-sq., W.C.).—5 P.M. Dr. Morgan Dockrell: Diseases of Sebaceous Glands.

Notes, Short Comments, and Answers to Correspondents.

EDITORIAL NOTICE.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

THE HYGIENIC ASPECT OF WOOD PAVEMENT.

M.R.C.S.—If our correspondent will refer to THE LANCET for Aug. 24th, 1895, p. 474, he will find a report of Mr. Wynter Blyth concerned with the question he asks. From this it would appear that asphalte is the most satisfactory form of paving from a health point of view. Wood pavement undoubtedly does get saturated with ammoniacal products, and gives off offensive smells in hot weather, but we do not think that it is worse in this respect than macadam, which is the other alternative to asphalte.

W. J.—There is much variety in the scale of payment of locum-tenents. They are certainly of very variable value. Some are very dear at three guineas a week, and some are worth five. Much, too, depends on the value of the work which they have to do. The fee to be charged by a principal for his assistant sent to be in the house of a patient night and day must be determined by the principal himself, after reckoning the inconvenience and cost he has sustained and the extra remuneration due to the assistant for such unusual work.

Bene.—We consider it decidedly a breach of professional ethics for a medical man to let his rooms to an unregistered dentist and to refer patients to him.

"PRACTICE IN SOUTH AFRICA."

To the Editors of THE LANCET.

SIRS,—Will any of your readers kindly advise a medical man as to the drugs, clothing, &c., to take to South Africa? and also any other information will be appreciated.—I am, Sirs, yours faithfully,

Oct. 9th, 1895. SURGEON.

*** Our correspondent is referred to THE LANCET, Oct. 5th, 1895, p. 835, where, in a letter signed "M. D.," he will find a large amount of useful information as to the questions he asks. With regard to clothing, South Africa is a large district and varies in climate in different parts so that we can hardly advise on this matter without a little more detailed information as to what part our correspondent is going to.—ED. L.

C. B. (Darton).—There is no usual custom. The delay in payment is not, in all probability, the clerk's fault, for he is only the paid servant, and the date of disbursements may be regulated by the date at which his accounts are audited—a date not under his own control. This, at any rate, was the explanation received by another correspondent who made a similar complaint to us. But the fact that the clerk cannot pay does not excuse the want of courtesy in withholding an answer, and our correspondent is advised to write to the chairman directly, and ask that his communication may be attended to.

Dr. Yarrow's communication will receive attention.

IMAGINATION.

A PROVINCIAL journal lately had an account of an inquest upon a child who died in a parish in Norfolk. The report stated that the child died on her return from school, a doctor having been sent for, that a post-mortem examination was made, and a *whole apple* discovered in the child's stomach. Apples, of course, vary in size as much as lumps of chalk, but still we fancy no child could swallow a whole apple unless he or she had a distensible head like a snake. But the facts are as follows: The child was taken ill on a Wednesday and died on the Thursday, no medical man having been sent for. At the post-mortem some pieces of egg, bread, and fragments of apples were found. The cause of death was diarrhœa, a complaint which has been very prevalent of late in the district. We are sorry to spoil a good story, but the fervid imagination of the lay reporter is apt to lead him astray.

Octogenarian.—The connexion between prurigo, a not uncommon source of trouble to persons of advanced age, and emotional or mental trouble is very well known, and continued mental depression would certainly render the neurosis more obstinate to treatment.

Mintern.—We do not, under the circumstances detailed, consider the charge exorbitant.

DROWNING FOLK-LORE.

To the Editors of THE LANCET.

SIRS,—Replying to your correspondent's query in THE LANCET of Oct. 5th, 1895, I beg to say that by searching the up-to-date indices of *Notes and Queries* "Teignmouth" will find a mass of references and information. Sir Walter Scott, Sir Thomas Brown, Miss Braddon (in her novel "Joshua Haggard"), Tylor ("Primitive Culture," vol. i., pp. 97-100), and Edgar Allan Poe ("Essays of Mystery and Imagination") also have referred to this subject. The most damaging and dangerous are the cruel superstitions *re* (1) the bad luck supposed to follow those who rescue the drowning or touch drowned corpses; (2) the landing of, or throwing up of, drowned corpses upon banks, piers, &c., absurdly alleged to injure the local fisheries by frightening the fish away from the district; (3) the ridiculous belief that the rescuer of the drowning is afterwards legally bound to maintain the person or persons whom he has rescued from the waters; and (4) various other superstitions which tend to frighten and hinder the ignorant from attempting to rescue the drowning.—I am, Sirs, yours truly,

Brighton, Oct. 5th, 1895. J. LAWRENCE-HAMILTON, M.R.C.S.

To the Editors of THE LANCET.

SIRS,—In answer to "Teignmouth's" query as to the position of the drowned bodies of the different sexes, I can assure him that the belief is held widely in nautical circles. I have confirmed it in my own experience on more than one occasion. Sailors explain the male position from the relaxed limbs, and the female from the larger mammæ and more prominent abdomen reducing the specific gravity, the larger and heavier thighs and buttocks placing the centre of gravity more posteriorly. This is, I think, reasonable, but I also believe the shape of the female thorax to be an important factor.

I am, Sirs, yours faithfully,

Harrogate, Oct. 5th, 1895. V. BATESON.

To the Editors of THE LANCET.

SIRS,—"Teignmouth" will find the following passage in Dixon Mann's "Forensic Medicine," pages 53 and 54: "Dead bodies usually float with the head and extremities below the water level; the bodies of men in the prone posture, those of women—on account of the adipose tissue of the breasts and abdomen—in the recumbent posture. In the one case the back, and in the other the abdomen, is at or above the water level." I am, Sirs, yours truly,

Oct. 5th, 1895. F. A.

To the Editors of THE LANCET.

SIRS,—In answer to "Teignmouth" I venture to suggest that the bodies of drowned women float face upwards because of the buoyant adipose tissue of the mammary region. May not the face downward position be determined in men by their predominant supply of gluteal fat? I am, Sirs, yours faithfully,

Wilton, Wilts, Oct. 5th, 1895. WM. WOODWARD.

I. C.—1. The fact that our correspondent actually was in charge of the practice for a period is proof that an arrangement of some sort was made, and therefore payment of some sort would be due for service done, unless that arrangement was broken through by the employé.—2. We do not think that "usual custom" is sufficiently strong in this case to make our correspondent consider himself entitled legally to any particular rate of payment, but the sum he has mentioned is a fair one.—3. We cannot give the desired definition; but it does not appear to us that any slight upon the social position of the locum-tenent was intended by the employer. We conceive the practitioner's attitude to be based on the idea that as the locum-tenent threw up his position his employer was absolved of all liability towards him. This is not quite tenable from the statement placed before us; but anything more decided than that cannot be laid down from facts supplied by one side only. Cannot a mutual friend or the agent who introduced the parties to each other be constituted amicable arbitrator?

Ballynafeigh.—We do not see that the evidence was required.

SNAKE VENOM AND ITS ANTIDOTE.

APROPOS of this subject and of the experiments of Professors Calmette and Fraser, a correspondent calls attention to the fact that one of the first communications, if not the first, published on the subject appeared in THE LANCET in 1884—Feb. 23rd and March 8th, pages 371 and 456 respectively—from a correspondent writing under the *nom de plume* of "Incognito."

J. L. A. H.—We agree with our correspondent. The subject is one upon which we have often spoken, and shall continue to speak.

Mr. Chas. H. Callanan's communication is receiving our attention.

Mr. Robert Martin is thanked for his letter.

A FEMALE MEMBER OF THE ARMY MEDICAL STAFF.

To the Editors of THE LANCET.

SIRS,—There is a tradition to which I have seen an occasional reference in English books that there was, one or two generations ago, in the British Army, a medical officer who attained high rank as such, and who was found to be, post mortem, of the female sex. The name ascribed to this person in the references which have fallen under my eye is sometimes James Barry, sometimes —— Macleod. Will you please inform me whether this story rests upon any credible foundation or is the mere figment of an idle brain?

Your obedient servant,

GEORGE A. BRIGHT, M.D., U.S. Navy.

U.S. Naval Hospital, Washington, D.C., Sept. 30th, 1895.

*** We can recall the following instances of concealment of sex in the Services—first, that of Mary Anne Talbot, the female sailor, and she did not belong to the medical department. She was, indeed, a very disreputable though courageous adventuress, and fought as a soldier under the Duke of York in Flanders, and as a sailor under Earl Howe of June 1st memory. She was an inmate at different times of Haslar Hospital and two or three metropolitan hospitals without revealing her sex. Then there was Christiana Davis (born 1667, died 1739), who fought in the Marlborough wars. She was wounded and in hospital several times without her sex being discovered. Mary Read and Ann Bonney fought as pirates about 170 years ago, and though their exploits may be mythical their real existence is undoubted. Probably some of our readers can inform us and our correspondent with certainty about James Barry. We have read many allusions to her, but none in any reliable quarter.—ED. L.

A QUERY.

To the Editors of THE LANCET.

SIRS,—Where can I see carried out or obtain the best information on the following subjects: (1) massage, (2) medical electricity, and (3) the Weir Mitchell treatment? I am, Sirs, yours truly,

Oct. 7th, 1895. POST-GRADUATE.

*** Our correspondent will obtain the information he seeks in the following works:—1. "Massage," by Dr. J. Symons Eccles.—2. "Medical Electricity," by Dr. Lewis Jones.—3. "Fat and Blood," by Dr. Weir Mitchell.—ED. L.

"HOMES FOR CHRONIC MELANCHOLIACS."

To the Editors of THE LANCET.

SIRS,—In reply to G. P.'s letter in THE LANCET of Oct. 5th, I think he will find what he requires at the Home for Invalid Ladies, Burntwood-lane, Tooting, S.W.—I am, Sirs, yours faithfully,

Sydenham, Oct. 8th, 1895. G. FORBES GAITSKELL, M.R.C.S.E., &c.

ERRATUM.—In the annotation headed "Deaths under Chloroform" in our issue of last week occur the words, "The chloroform was administered by the medical superintendent" (of the St. Saviour's Union Infirmary, East Dulwich). Dr. Elwin Hunt, the medical superintendent, writes to us that he was away for his holiday, so could not have administered the anæsthetic.

During the week marked copies of the following newspapers have been received:—*Manchester Guardian, Galloway Gazette, Ayrshire Post, Midland Free Press, Daily Chronicle, Scotsman, Times of India, Folkestone Express, Cheshire Observer, Liverpool Courier, Birmingham Gazette, Pioneer Mail, Yorkshire Herald, Glasgow Evening News, Newcastle Daily Leader, Brighton Gazette, Builder, Western Express, Architect, Yorkshire Post, Sanitary Record, Bristol Mercury, Durham City Advertiser, Liverpool Daily Post, Hampshire Herald, Leeds Mercury, Weekly Mercury (Plymouth), North British Advertiser, New Zealand Times, Liverpool Journal of Commerce, Local Government Chronicle, Hertfordshire Mercury, Mining Journal, Weekly Free Press and Aberdeen Herald, Reading Mercury, City Press, Coventry Herald, Weekly Dispatch, Surrey Advertiser, Cape Times, Glasgow Herald, Kendal Mercury, Elgin Courant, West Middlesex Standard, Citizen, Eastern Morning News, The Realm, Indian Daily News, Oswestry Advertiser, Batley Reporter, Fife Free Press, Hampshire Advertiser, Loughton Monitor, Australian Medical Journal, Derbyshire Times, Eastern Daily Press, Science Siftings, Shrewsbury Chronicle, Essex County Standard, &c., &c.*

An Introductory Lecture

ON

THE FOUNDATIONS OF MEDICAL SCIENCE.

Delivered at King's College Medical School on Oct. 4th, 1895,

BY LIONEL S. BEALE, M.B., F.R.C.P. LOND., F.R.S.,

JOINT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN KING'S COLLEGE, LONDON, AND PHYSICIAN TO THE HOSPITAL.

GENTLEMEN, — The extraordinary advance which has characterised nearly every department of science during the past fifty years can hardly be said to have helped the solution of that most important of all problems, the very foundation of natural science—the nature of life. To us engaged in the study of disease and the relief of suffering it is—and from more than one point of view—a fundamental question, one which from the earliest times has been regarded by the medical profession with the keenest interest. Time after time scientific enthusiasts have announced in the most confident terms, and for more than forty years the public have been assured again and again, that at last the mystery had been solved or was so near solution that it might be considered as practically settled. Among scientific workers and thinkers, however, the divergence of opinion as to the real nature of life has been, and is, so great that we are still uncertain how any living thing is formed, how it grows, what is the exact nature of many diseases, and in what manner the action of many of our medicines is to be correctly explained; while, notwithstanding great progress in investigation, many morbid changes and phenomena connected with the healing of wounds and the repair of injuries have yet to be cleared up before we shall be able to say that the nature of vital processes is understood. The very foundations—the first principles of all living nature, the exact differences between the living and the non-living state—have still to be established. Even the broad differences between a particle of matter which is actually living and one that has just ceased to live have not been ascertained, and our physiology, pathology, and medical science rest upon no certain basis. Mental operations have received various explanations, but not one that has been offered adequately accounts for the facts, while vague and uncertain data and conflicting interpretations of facts form the foundations upon which uncertain and perpetually changing philosophy has been constructed. So strong, however, is the conviction of some with regard to the truth of the physical doctrine of life and the generalisation that the living and non-living are one, that not a few would modify our systems of government and education in order to bring them into accordance with certain fanciful speculations upon the religion, morality, and civilisation of the future when physical doctrines shall be universally accepted and taught.

So determined has been and is the set of opinion against the idea of the operation in living beings of anything in its nature distinct from physical or chemical change that I have long hesitated to press a contrary view, notwithstanding that facts and arguments in all departments of living nature give to it very strong support; while, on the other hand, the favourite doctrines still taught are contrary to all living nature, and to make them popular it has been necessary to invent a new nature—a nature which from the first has been shown to be impossible. Lately, however, a change has come over men's views. Not a few have begun to doubt whether the purely physical doctrine of life is supported by facts, and at last the distinguished President of the Chemical Section at the Ipswich meeting of the British Association has dared, not only to express his doubts concerning the purely physical doctrine of life, but has gone so far as to plead "for a little more vitality." I heartily join in his plea, and have for many years hoped that ere long we should be permitted to admit the operation of a vital, constructing, arranging, guiding, and regulating power working in everything that has life. I have endeavoured to show exactly where this power operates and upon what, and have drawn attention to the fact that the living matter or "bioplasm" possesses very similar powers in all living things, from the lowest to the highest. For the most part the plea has been in vain, and overwhelming authority has declared for the opposite view, and that those who differ, being weakest, are to go to the wall.

This question of the nature of life forces itself upon our consideration in all our deeper medical and physiological inquiries and in all attempts to decide upon the foundations of natural knowledge. Not only are intellect, thought, and the countless workings of the mind inexplicable upon physical doctrines, but the movements and growth of the very simplest living forms are due to far more than is comprised in purely physical and chemical changes. Is not life-power the real, directing, controlling, regulating, and selecting agency in every form of the living? How can we accept the proposition that from non-living atoms and their properties is somehow evolved a power which determines the arrangement of these very atoms, which places them in already determined positions, that tears them away from one another and then brings them within the sphere of their influence so that new and totally different substances result? Could watches and engines make themselves, and multiply, regulate, and direct, set themselves in motion, and stop when they willed to do so, some comparison might be made between machines and living matter. I feel sure that all intelligent persons will agree with me in thinking that the time has arrived when this matter should be thoroughly reconsidered. The influence of vitality upon matter as a guiding and directing agency—as a power by which the elements of matter may be torn away from one another, rearranged, and caused to recombine in a way unknown to physics and chemistry—has yet to be recognised, and, if possible, investigated. That this power is transmitted from living particles to lifeless ones, which then live, is certain; equally certain is it that all living matter is clear, transparent, structureless, and as colourless as pure water. These are the characters of the simple substance in which vital changes are effected without machinery and without any apparatus. This living matter or bioplasm is, I believe, the foundation of all living nature, the seat of all vital phenomena in health and disease, and the only substance in nature possessing powers correctly termed vital. Is there not evidence that in every kind of living matter the elements of the substance that lives may be separated and rearranged in an order determined beforehand, and in such a manner that definite compounds result, and structures evidently designed for definite purposes are formed to do certain work? Have any such phenomena been explained by physics and chemistry? Consider whether any machine has been constructed that can perform work and be kept for any length of time in working order without the designing, regulating, managing power of the living mind. Where is the laboratory that performs chemical operations without the chemist? And where is the matter that can be subjected to analytical and synthetical operations without the intervention of some living agency? And yet it has been affirmed again and again that the living cell is a lifeless laboratory, where work of the most complex kind is carried out without any designing, directing, or controlling agency whatever. It is often assumed that substances of chemical simplicity are more easily changed in vital action than bodies of great complexity of composition; but as far as we have evidence complexity and simplicity of composition are equally overcome by living power. The change seems to be carried out in all cases in the most perfect manner, and very quickly. The view of the building up from simple to complex is not justified. The atoms seem to take up their appointed positions and relations as if impelled by irresistible power, and according to the same principles in every case, from the lowest to the highest organisms.

The members of the profession and all students are to be congratulated upon the addition, during the past three years, of a new subject to those which have long formed the basis of medical education. The careful study of elementary biology must now be taken up by every medical student in the early part of his course. He has to work with the microscope and to become familiar with the use of instruments for delicate research which were not known to the advanced investigators of fifty years ago. Every student acquires real knowledge of the minute structure of the body, and may form his own conception of the general nature of the wonderful changes characteristic of living things, from the lowest organisms to man himself. I hope you have all

Digitized by Google

seen what happens when a particle of living matter, say, of an amœba, exhibits what we call vital movements, and have observed portions moving away from the general mass. Such portions, becoming detached, begin a new and independent life, taking up nutriment on their own account, and growing like the parent organism from which they have been detached, or have detached themselves, and at length increase and multiply and at last die, like all other things that live. Some have affirmed that this living matter is "like" a mixture of oil and mucilage, but those who have studied practical elementary biology will not be misled by such a "likeness." Would that people generally could also study some of these simple living organisms and learn the differences between that which lives and assimilates, and grows and dies, and that which does not live. No one who had thought over what he had seen would be persuaded to assent to the proposition that the clear structureless living matter should be regarded as a form of machine, molecular or otherwise. When you examined this living matter under a high power I am sure you must have felt astonished that any one could speak of such a thing as a mechanism or as a laboratory. The moving projections or diverticula just alluded to, like those of leucocytes and pus and mucus corpuscles, are well deserving of your further attentive study. Watch carefully the movements and notice how very clear and transparent is the moving matter. In some you cannot discern a single granule even with the aid of the highest powers, and I think when you do see granules and carefully study their movements you will agree with me in the conclusion that it is not in these visible granules that the moving power resides, but that the visible particles are moved by the clear, soft, structureless substance of which the diverticula consist. The process of growth may continue by the taking up of non-living matter by the transparent, moving, living substance and the communication to it of amœba life, through generations. The process has proceeded possibly for thousands (?) of years, but whether an atom of the matter of the parental organism remains, except for a very short time as a constituent part of the detached descendant, seems to rest upon too fanciful a basis to entitle the living changing matter to be regarded as *immortal*. Think over what you have seen and consider how the wonderful movements are occasioned, how the living matter communicates its powers to the non-living and grows and multiplies. Can it be merely chemical change or mechanical action that produces the result? When and what is the machinery said to be present, and how is any "molecular mechanism" to be demonstrated in such transparent substance? *Authority* alone steps forward and insists upon laws and properties and tendencies, declares to us what we are to believe, and prophecies what our successors will discern in the future.

Before the year 1860, after having carried on observations upon the tissues of plants and animals in many departments of living nature, and from the earliest period of development to the fully formed state and into old age, under the highest magnifying powers (from 700 to more than 2000 diameters) and with great advantages as regards the preparation of specimens, I was led to draw a distinction in each tissue, organ, or organism between the living growing formative matter and that which had been formed and could not reproduce itself or give rise to more formed matter. I was gradually led to the general conclusion that every form of the living growing matter was absolutely distinct from every kind of the resulting formed matter produced by it, and, further, that the influence upon the non-living pabulum was peculiar and belonged to all living matter, but to this only, and that it was not comparable with, or allied to, any other known property, power, or action of matter. These conclusions were illustrated in detail and were published in 1861. The preparations were shown to my class of physiology in this College and during lectures at the Royal College of Physicians of London, and further discussed in memoirs published in the Transactions of the Royal Microscopical Society, and in several works published at that time and since. It seemed to me that there were no indications whatever of the faintest analogy between the two kingdoms of nature—the living and the non-living,—no indications of any gradation from matter in the non-living state to that of life, while all living matter, from the very lowest to the very highest, exhibited certain common characters, being always colourless, structureless, capable of independent movement as a whole or in part, capable of growth, with a power of selecting certain substances and rejecting others, having structural formative power and powers of effecting chemical change, rendering it certain that the origin of matter so endowed was not direct from the non-living, and that this doctrine sooner or later would have to be abandoned. The warmest advocates of the latter view have never given adequate reasons for the faith they professed, or answered the many objections advanced against the conclusions they accepted and taught. All the particles of living matter actively concerned in the formation of tissues and organs, easily seen under a power of 200 diameters, are less, and most of them considerably less, than the $\frac{1}{1000}$th part of an inch in diameter. In the absence of such living particles nothing can be formed or secreted. If we are to form any accurate conception of the actual phenomena which occur when some of the matter of these minute living particles is resolved into tissue or secretion, it is necessary to study the matter very attentively with the aid of the highest powers, and then we can expect only to learn some of the broader changes which occur. The actual conversion probably occurs in particles of matter far more minute than can be discerned with the highest powers at our disposal. Most important facts, however, have been demonstrated with reference to the movements of many of these bioplasts. Where fibrous or other tissues are formed which are to be laid down in parallel lines the fibre is as it were spun off as the particle of living matter (bioplast) moves upwards or downwards along the tissue already formed, and thus fibre after fibre is added to those already existing. In some tissues the bioplast moves round and round the cell cavity, thus forming concentric fibres or layers. Such bioplasts, evenly distributed through all the tissues and organs of the body, even in the solid bone, take part in the formation of the tissue around, may exist through life, and change very slowly in health, most of them getting smaller as age advances. These are instrumental in establishing the passage of fluid to and fro in the interstices of the tissue. By this continual flow the integrity of the tissue is preserved, and the occurrence of degenerations prevented or postponed. Anything favouring the passage of more nutrient fluid than the very small quantity required by these slowly living particles favours their enlargement—they live too fast. They increase in size, and this change is constant in every form of inflammation and fever. With the enlargement there is invariably rise in temperature of the surrounding part and of the blood as it traverses the nearest capillaries. When this change, as in fever, affects the bioplasts of many tissues of the body and is widely distributed the temperature of the whole volume of blood is, as we know, raised several degrees, but falls with the diminution of the febrile symptoms, as the bioplasts return to their ordinary condition. If in ordinary inflammation the process continues and increases, the bioplasts give off diverticula which may be detached, and at last "pus corpuscles" result, and the adjacent structures are destroyed. In all pathological changes these bioplasts take part. The health of the body depends upon the normal state of the bioplasts, and movement and changes continue while life lasts. Their life is destroyed by many poisons, notably by hydrocyanic acid, the proportion of 1 in 100,000 in the blood being probably sufficient to destroy the life of adjacent bioplasts in a few seconds. You must have seen multitudes of these bioplasts disseminated through the tissues which you have examined, and have, no doubt, studied their arrangement in different tissues and organs, though, perhaps, from their being perfectly colourless you may not have regarded them as the most necessary part of the organism. Without them no tissue or organ could have been formed, could have preserved its integrity, or, in case of injury, could have been repaired. They are the life of the body, and without them nothing can live; they constitute the living part of the body—that is, the matter that dies. In cases of fever and inflammation, and in various conditions in which there is increased flow and facilitated access to the bioplasm of nutrient matter in any tissue or organ, one sees, after the altered state has lasted for a short time, arising here and there in various parts of the bioplasm minute dots, which gradually become large enough to be seen easily, and are known as nuclei. If the process continues some of them become much larger, and in them new points appear (nucleoli). This is an example of true evolution, as the bodies in question are new centres of living matter, which arise in already existing and perfectly structureless bioplasm.

Not only as long as life lasts is the substance of which living matter is composed in constant movement and portions caused to change in position, but the very elements of the matter, however strongly they may have been united in the

Digitized by Google

non-living condition, are caused to separate, and not only are they rearranged, but they are rearranged in a definite and predetermined manner which differs in different organisms and in different tissues and organs of the same organism. Such movements, of course, can only be represented to the mind, since the movement spoken of and the affected particles themselves are far beyond the present range of our vision, assisted as it may be to the utmost with the aid of very high magnifying powers. The movements we are considering in very minute particles of living matter take a general direction from centre to circumference, and the places of those which have taken a centrifugal course are taken up by the pabulum, the flow of which is centripetal. It is, in fact, in these centres, far removed from our powers of vision, that life power seems to be communicated to the matter, and here the non-living matter begins to live. Life causes elements, however strongly combined, to separate, and overcomes the physical and chemical attractions of elements in combination. Life is able to raise particles above one another in a manner not explained. Of the rearrangement of the component atoms of matter, and of the alteration of their relation to one another during the living state, there can be no doubt, but how this is effected has not yet been ascertained. This rearrangement is different in the different kinds of living matter, and results in the production of certain special substances, constant as regards living matter of the same kind under the accustomed natural conditions. So far, observation and experiment have proved that this wonderful power has been directly derived from pre-existing living matter and may be transmitted to succeeding particles of matter without loss, but in certain instances with some modification, temporary or permanent.

It seems to me that as soon as you realise the appearance and movements of this living matter and the broad facts connected with it, its powers of selection, of growth, of chemical analysis, of direction, and rearrangement of elements, you will naturally require the strongest evidence before you accept from authority, however distinguished, the purely mechanical or chemical view. In the physical and chemical world there is nothing to approach it or that will in any way compare with living power. Every chemist must, indeed, long to discover the secret of the wonderful analytical and synthetical operations of living matter working without apparatus or chemicals, silently, perfectly, and continuously, in darkness as well as in light, in what we call cold as well as in heat, in winter as well as in summer. Is it not wrong in the face of what we know and have known for many years on the part of any authority to persist in the effort to make people believe that there is no mystery whatever, nothing to be discovered as regards these wonderful operations of nature which proceed in all living—that they belong to the physical category, and that, in fact, we are on the eve of the complete solution of the vital problem and of the demonsrration of the manner in which life works? In truth, we are farther off than ever from this discovery, because we are daily becoming better acquainted with the increasing number of facts as well as the difficulty of investigating them, which separate the knowledge we long for from the knowledge we possess. Is it right, in the face of such utterly inexplicable endowments of living matter, to suggest that they can be in any way dependent upon or derived from the properties of the matter, which for the time is the seat of operation of the endowment, or even to hint that our present scientific knowledge justifies the belief that they will receive a purely physical explanation? In the whole range of knowledge can one fact be pointed out which is allied to, or comparable with, or can be properly placed in the category to which these vital characteristics belong? Is there one of the remarkable powers of living matter which has yet received anything approaching an adequate explanation? Is there anything in the non-living world in any way comparable with the ordinary changes which have taken place in every living particle that has ever existed?

If any apology is due from me for troubling you with all these details, I am sure you will pardon me for desiring that I should give a brief account of them in the college in which I have been brought up and in which much of the actual work upon which my views rest was done. But there is another reason why I particularly wish to call attention to this view of vital action at this time. With reference to the powers of living matter, there is nothing more interesting and important than its chemical influence. One is amazed at the wonderful changes effected in composition brought about while matter is in this living state, and the extraordinary rearrangements silently and invisibly effected in the position and relation of the atoms of the living substance. I am particularly gratified at being able to say that this matter is at last being seriously considered and is receiving the attention it has long deserved. A distinguished chemist has recently expressed himself in favour of "vitality" and pleads for "a little more vitality in the chemical functions of living organisms." This is the first time I have seen anything so encouraging from the chemical side, and I hope Professor Meldola's remarks will be widely read by all interested in physiology and medicine. In his opening address as President of the Chemical Section at the Ipswich meeting of the British Association, which was published in *Nature* of Sept. 12th, 1895, p. 483, you will find some very pertinent remarks on the chemistry of living things, well worthy of the attention and criticism of those who still advocate physical and chemical theories of life. Professor Meldola freely acknowledges "that we have not yet solved the enigma of life," and suggests that physiologists have been led "to undervalue the importance of their *prime agent*" and pleads for "more vitality." Professor Meldola, in fact, without committing himself to vital power, certainly goes much farther in this direction than any other distinguished chemist has hitherto ventured. He considers that there is a great difference between laboratory and natural processes, and speaks of "the mystery that still surrounds the chemistry of the living organism."

The tendency of these views is very different from that of any of the doctrines hitherto advocated by chemists, and I venture to commend this part of the learned Professor's address to the careful notice of all interested in the advance of physiology and medical science. The President of the Section of Chemistry further observes that "everything must pass through the vital mill." In other words, everything formed in every living organism must pass through the state of living matter or bioplasm before it can be converted into the particular predetermined chemical substance. The phrase "vital mill" is, however, objectionable, as no mill is alive, and nothing living has the machinery of a mill. In the vital substance the atoms are made to take their places for the formation of special compounds without friction, without machinery, without reagents, without apparatus. The principles upon which the changes are carried out are totally different from those which obtain under any other circumstances known. If vitality, for which I have been pleading for more than thirty years, be granted, we shall be much nearer the explanation of vital phenomena than is supposed. The observations of the President of the new Botanical Section, Professor Thiselton Dyer, Director of Kew, upon this subject are very satisfactory to me, for many years ago I also drew attention to the contrast between the way in which chemical changes were effected in living matter and in the laboratory. The President says: "The plant produces a profusion of substances apparently [why "apparently"?] with great facility which the chemist can only build up in the most circuitous way." I am delighted to find that at last this important question has a chance of being considered from this point of view, and that at last we may hope for a "little more vitality" to assist us in our consideration of the real nature of vital phenomena.

So far, then, we seem to have arrived at this—that the matter of the body actually living can be distinguished from the material which is formed by changes occurring in any portion in which vital phenomena have ceased. For instance, in a growing "cell" of epithelium the central part is structureless and is alive, and its particles can grow and multiply. The outer part has structure, but no longer manifests vital phenomena. It cannot produce matter like itself, or grow, or select nutriment, or exhibit spontaneous movements. Just at the point where the formed material and the living matter touch, particles of the latter from time to time cease to exhibit vital changes, and the resulting products become formed material which is added to that already produced. Such changes occur everywhere in living organisms, from the first to the last moment of existence, whether "high" or "low," "simple" or "complex." *Vital change* is one thing, physical and chemical change another, and no particle of matter is the seat of these two classes of changes at the same moment. But there are other wonderful powers associated with the living condition, known to all but understood by no one, some of which I shall now briefly refer to. With regard to the marvellous power which a speck of living matter may transmit without loss to descendants

Digitized by Google

during centuries, only think of this: the oldest variety of pigeon, bred for many generations without loss, and perhaps with improvement, of its remarkable characteristics—and bear in mind not only as regards colour, form, and number of feathers, but widely diverging from its original progenitors as to the size and characters of bones, muscles, nerves, and other tissues; as to habits, manner, and disposition, as to powers of flight—in fact, as to many particulars which would lead us to regard it as a true species far removed from the rock pigeon—in short, having little in common with that species—nevertheless carries, apparently fixed and unalterable in its organisation, not a new tendency, but an inalienable compulsion if left to nature for its offspring to revert to the ancestral characteristics; not immediately, but after a few generations its descendants exhibit the original specific characters, having lost all traces of the variety which but a few (often only three or four) generations before might have been regarded as a definite species of pigeon. And, further, think of this—that every rock pigeon, generation after generation, has possessed deeply ingrained, as it were, in its organisation the power of transmitting to descendants the capacity of giving origin to any or several varieties of pigeon that are known, and perhaps to many more varieties not dreamt of, and at the same time to every variety the power of reversion to the original species, if only each individual is allowed to choose its mate as in a natural state. Consider the constancy and, on the other hand, the wonderful plasticity of the organisation of this familiar but remarkable bird. Contemplate the wonderful power of change from, and the more wonderful power of reversion to, the original type transmitted through generation after generation and retained through centuries, the only medium being a speck of matter so minute that it would not be indicated by a very delicate balance, and tell me whether you think it probable that the powers referred to are due to the original material properties of the fragment of matter concerned or whether this acts only as a carrier of the marvellous power belonging to the living world only and originating in the infinite. Never before the present time was there any possibility of approaching the thorough investigation of the important question of life. Our much wider range of knowledge concerning the structure and action of many living organisms widely separated from one another has, in fact, enabled us to consider the question from many new points of view; and, although the issue between contending parties is perhaps more pronounced than ever, the probability of arriving at the truth has immeasurably increased, if, indeed, it has not already reached something approaching certainty. It is curious that, although knowledge of minute structure and of the actual phenomena characteristic of living matter has been widely spread, the important question of the nature of life and its resemblance to, and differences from, all physical and chemical actions known has only been very imperfectly debated. One would think that the inquiry lay far away from the paths familiar to most educated persons, but the most important points bearing upon the inquiry can now be made intelligible to educated minds without much difficulty, so that many thoughtful persons may be able to form a judgment of their own, at least concerning the direction in which the truth will probably be discovered.

Among the broad and well-known facts, then, not to be explained by the physical view of vital action is the vast subject of heredity so remarkable in every department of nature, both for the long periods of time of its continuous operation and for the magnitude and enormous importance of the results when considered in connexion with the very minute quantity of matter concerned. Is the transmission of characteristics of minute structural details of extraordinary constancy handed down from generation to generation for hundreds or thousands of years by the very minute particle of matter which we know to be concerned in the process to be attributed to the physical properties and chemical composition of the matter involved or to vital power communicated to this from the immediate predecessor? Of all vital attributes this is the most remarkable, and while some facts of living nature impress us with change and modification in descent, others astonish us with the extraordinary constancy of the transmitted characters. It is also certain that many of the most striking divergencies known to us are evanescent, and after a few generations ancestral characteristics reappear in all their intensity.

Our attention has been frequently and most forcibly directed to the fact of the likeness between very numerous distinct species of organisms, and especially in the case of man and higher vertebrata, during the latter portion of the developmental process, but little stress has been laid on the much more striking fact of the much closer resemblance during the early and earliest changes—the far more remarkable fact that at first, when the most striking phenomena of all life are actively proceeding, and the changes afterwards so prominent are commencing or being prepared for, no difference has yet been demonstrated between the particles of living matter instrumental in the production of living organisms eventually far removed from one another in all points. This fact has hardly been noticed, and yet who shall declare that there is really no difference or that there is anything approaching similarity or identity between the clear, transparent, structureless specks of living matter that represent the early stage of being, say, of mouse and elephant, of man and monkey, and as the changes proceed and growth goes on who will now dare to assert that they are to be accounted for by physics and chemistry only, or that there is no evidence of the constant activity and directing power of another factor—no less than the most tremendous power above all else in living nature—life?

We have passed through a very widespread effort to convince us that our present knowledge of the facts of nature justifies all who allow their minds to be influenced by reason in abandoning their belief, not only in Christianity, but in the existence of infinite power. Moreover, this effort is not the work of a fanatical party determined to conquer or to die, but rather of men of exceptional intelligence as well as of power of leading other minds. Some of them regretfully acknowledge the decision at which reason has compelled them to arrive; but, having been guided by facts and reason alone, they accept, though with reluctance, the only conclusions which in their view the understanding can now accept. It is this supposed claim upon predominant reason—this positive declaration said to be enforced by facts of observation and experiment—that has influenced many and has led people to conclude that the old views can no longer be sustained and that our present intellectual position is absolutely different from any that has preceded. It is, therefore, urged that the opposition to religion at this time rests upon facts and arguments which have never, and, indeed, could not by any possibility have been, advanced before. In short, it is maintained that in consequence of new scientific knowledge the data upon which the truth of the religious ideas of the past was supposed to rest have been shown to be erroneous. He who believes in scientific truth must, if he acts according to the dictates of reason, abandon his old faith. This idea that the more recent discoveries in science have rendered impossible the acceptance of the religious doctrines formerly generally believed has undoubtedly gained many converts. The notion that it has been proved beyond doubt that the living and non-living are governed by the same laws, and that very long ago the living came direct from the non-living—in short, that the living and the non-living are one—has been widely accepted. Even those in doubt have been much influenced by the constant repetition of the statement that ere long all the phenomena of life will certainly be shown to be due to physical and chemical action only, and the dictum of Strauss, supported by Haeckel, that faith with its miracle has perished, must satisfy all whose judgment is swayed by reason alone. This notion that science must ere long somehow take the place of religion, though seldom expressed, has unquestionably influenced the views of some intelligent persons on the question of religious education, and it is more than probable that much of the recent opposition to religious teaching, culminating in the arbitrary withdrawal of the Government grant of £1700 a year which had been awarded to our college for five years, and of such vital consequence to our struggling institution, is also due in some measure to the change in general opinion in the direction indicated. It is sad, indeed, that some who have long been proclaiming freedom should have taken part in an effort to damage the interests of a college which has gained very high distinction by the original research and teaching of a distinguished scientific staff over a period of sixty years.[1]

We have now followed the phenomena common and peculiar to all living to the seat of their activity in living matter. In centres far more central than our present means of investigation will permit us to penetrate living particles communicate, and without loss, their marvellous powers to

[1] The grant has been restored since this was written.

Digitized by Google

some of the recently selected molecules of the non-living pabulum. It would seem that now for a time the ordinary properties of matter are held in suspense or are overcome. Here occur analytical operations of the most stupendous kind, which are carried out very quickly and in the quietest manner, without apparatus or reagents, and without resort to a high temperature. The matter which is the seat of these phenomena is as clear as water, structureless, and composed of very few elements which, if the matter dies, easily take the form of an albuminous substance with fatty matter and salts. During the living state the atoms of the matter, if there be atoms, may be torn from one another and made to take up new and definite relations, so that by synthesis there arise new substances with new properties, perhaps exhibiting structure and capable of performing purposive action of the most striking and at present inexplicable kind—motion, heat, light, electricity, being manifest in certain cases among other phenomena, while there are present no arrangements, conditions, or apparatus such as would enable us to develop these independently of the living. Here, then, as it seems to me, will be found the foundation not only of the principles of physiological, pathological, and medical science, but of that of the whole living world as distinguished from the lifeless cosmos. Here we must look for the initiation of all the changes characteristic of the living state. Account must also be taken of these peculiarly vital phenomena in discussions concerning consciousness, thought, and will, and the life that has been, is, and is to be. And may we not even hope that by further and deeper study of the phenomena of living matter under the new advantages of demonstration which we enjoy, and which are constantly progressing, some further light may be thrown by the increased skill of investigators of vital phenomena even upon the nature and relationship of material atoms in that boundless world of the non-living which ever has been and must be regarded alike by learned and unlearned with wonder and admiration?

An Address

ON

SEPTIC AND AUTO-INTOXICATIONS AS CAUSES OF DISEASE.

Delivered before the Wrexham Medical Society on May 10th, 1895,

BY WILLIAM CARTER, M.D., F.R.C.P. LOND., B.Sc., LL.B. LOND.,

PHYSICIAN TO THE LIVERPOOL ROYAL SOUTHERN HOSPITAL AND PROFESSOR OF THERAPEUTICS AT UNIVERSITY COLLEGE, LIVERPOOL.

GENTLEMEN,—During the last seven or eight years I have observed, and have drawn the attention of others to, a number of cases strikingly illustrative of the importance of the application of antiseptic methods in medical as distinguished from surgical diseases. These cases were all of them severe and for a time obscure; and the circumstance that similar ones that have recently come under my observation had baffled the researches of some most highly trained and skilful minds makes me hope that good may result from continuing to direct attention to the subject. I am the more encouraged in this hope from the fact that testimony has been sent to me from several different quarters of good having been done by the publication of the previous reports. When, therefore, the request was conveyed to me that I would address you I determined after a little consideration once more to revert to the subject. Reports of the earlier of the cases to which I have alluded were published in inaugural addresses which it was my duty to deliver as President of the Liverpool Medical Institution during the sessions 1888–9 and 1889–90, the titles of these addresses being "The Principle of Disinfection in Medicine" and "Illustrations of the Operations of Ferments in Disease." A further series of great interest, owing to the intensity, and in two instances to the long duration, of the disease, was published in an address given to the Birkenhead Medical Society on March 9th, 1894, and those now to be related will serve to continue that series and to illustrate further the principle of action on which their successful treatment was founded. That principle, briefly stated, is to thoroughly explore every accessible portion of mucous membrane or skin in all obscure febrile disorders, and, if any breach of surface is discovered, to heal it. Frequently the only proceeding necessary in order to bring about this healing process is completely to cleanse the ulcer or abrasion. If this can be effected by irrigation with water or salt and water nothing more need be done. Generally, however, it will be advisable to employ one or other of the more active disinfectants, and sometimes, as in the case to be brought before you presently, to remove a bit of necrosing bone or a fragment of slough which is keeping up irritation.

I wish particularly to draw attention to the fact, so well known to every one of us and which should convince us of the importance and soundness of this principle, that fever of a hectic type, leading ultimately to death from exhaustion, is every day being caused by the absorption into the system of our patients of toxines manufactured by crowds of bacilli tuberculosis, lodged on pulmonary ulcers. We know that these bacilli do not penetrate far into the tissues as they need oxygen for their development, and that if we could only get at their hiding-places we should be able soon to make short work of them and to put a stop to the febrile process. It is the inaccessibility of their places of concealment alone that enables them for the most part to defy us. But we know also that every now and then pulmonary ulcers which have served as nests for the breeding of these bacilli become healed, and that directly the healing has been completed the patients have begun to amend and have ultimately recovered. There can be no mistake whatever about such cases and about the sequence of events and its causes. The fact of the presence of crowds of bacilli in blood-stained expectoration may have been demonstrated microscopically; hectic fever and wasting may have existed for some time; the death sentence even may have been pronounced, and yet the patient may have recovered. But before he can have recovered the bacilli must have disappeared and the preliminary ulcer have healed. Such cases are, alas, but rare in any individual man's experience, but they are numerous enough in the history of modern medicine to make the fact secure. Yet it is singular that with such a fact before us we seem slow to believe that ulcers in other parts quite within the reach of a diligent searcher can serve as the lurking places of various kinds of microbes, where they may manufacture disease-producing poisons of a virulent kind for a long time together, until they are found out and dislodged, when the poison-making process is at once stopped and the patient gets well. The lesson I am most desirous of driving home, then, is that in every case of acute or chronic fever of an unusual character that may not be fairly judged to be caused by one of the recognised fever-producing diseases every accessible portion of the organism should be thoroughly explored, and if any ulcer is discovered that should be healed. I am persuaded that if this were done there would be fewer cases of what is called inexplicable temperatures, and I could not help wondering, and in the light of one of the cases which I shall now bring under your notice and of the comments made on it as well as of others which I have reported, whether all those cases alluded to in the discussion on that subject at the meeting of the British Medical Association of last year were, after all, quite so inexplicable as they were thought and stated to be. A fact to be particularly borne in mind is that the abraded surface need not be a large one. An ulcer of a very small superficial extent is quite large enough to serve as an open door for the introduction of sufficient toxic material to cause serious symptoms, and in all probability the toxines are the chemical products of active microbic life on the site of the ulcer. Nor need there be much pus formation. Here again the ideas derived from our observation of pulmonary disease of a tuberculous type probably constantly mislead us. The intensity of fever is so commonly proportioned to the amount of purulent expectoration in cases of phthisis that we are apt to think that the one cannot occur without the other. The fact is, however, that there can be much pus without fever and much fever without pus. Pus has but to slowly accumulate even to a large amount out of reach of atmospheric air and there may be no obvious rise of temperature, as is seen in what were formerly termed by surgeons "cold abscesses." I make this remark for a reason which will be apparent when I relate one of the most remarkable of these cases, to which I will now ask your attention. I ought, however, to preface

Digitized by Google

the narrative with one further remark. It relates to the frequency with which such ulcers occur in the nasal passages and in the associated neighbouring parts. This should excite no surprise, but is, indeed, just what we might have anticipated. The dark and sinuous passages caused by the turbinated bones in the middle and posterior nares form admirable lurking-places for bacilli, difficult of detection and still more difficult sometimes of irrigation, yet affording all the most favourable conditions, such as moisture, warmth, and free admission of air, for their development.

On the afternoon of May 3rd, 1894, I was requested to see a patient, a medical man, residing at Liverpool, in consultation with Dr. George Wilkinson, who had been attending him for some days. I found him very much depressed and anxious about his condition. He was complaining of severe headache, which was aggravated by light, of feverishness, and of feeling generally very ill. The temperature was 104·4° F. and the pulse quick. The history given was that he had been well up to April 28th, on which day he became unwell, had a chilly sensation and much nausea. On the following day he was said to have felt well until the evening, when headache, especially around the left orbit, distressed him. He awoke at 2 A.M. on May 1st, the pain being then very severe; he vomited, and was restless till the morning was somewhat advanced. He then felt better, but the temperature was found to be 101·8° and by the evening 102°. He passed the day fairly well and was said to be better on the morning of the 2nd, when the temperature had fallen to 99°. As the day wore on he again became worse. The headache returned with much throbbing, and the temperature rose to 103°. During the night he was restless, and in the morning the temperature was still 103°, and as he felt no better I saw him in the afternoon with Dr. Wilkinson. My attention was attracted to a moderate injection of the left eyeball, and on pressing over this and the bridge of the nose I gave pain. On examining the nostril itself as well as the pain and restlessness of the patient permitted I found it also red and injected, and ascertained that inspissated blood-stained mucus had been discharged from it. Five grains of calomel were prescribed, a simple febrifuge mixture which Dr. Wilkinson had ordered was continued, and at my urgent desire it was agreed that boric acid should be used as a snuff several times daily, and some time after such use of it a warm solution of boric acid should be injected into the nostril. If inspissated mucus plugs the nostril, within three or four minutes of using a snuff of boric acid a free secretion is established which loosens and detaches it so that irrigation of the denuded membrane by any antiseptic solution can then be carried out. About two hours after my first visit I received an urgent request to see the patient again, as it was thought he was worse. I again met Dr. Wilkinson in consultation. Except that the temperature was slightly higher, and there appeared to be a little delirium, the patient's condition was as before, and as the local antisepsis had not yet been carried out we made no alteration, but agreed to act on our previously formed intention of seeing him again at one o'clock on the day following. At 10.30 on the following morning, however, I received a telephonic message to the effect that he was so much better that it was felt to be unnecessary to trouble us to call. I subsequently learnt that after using the snuff and irrigation he had a fair night; that on the following morning the temperature was 99°; that he felt much better all day; and that there was some discharge from the nostril. On the following day the improvement was more marked, the morning temperature being normal. The local applications were steadily persevered with and in a few days the patient became well, there being during those days only a very slight evening rise of temperature. After the recovery I was informed that two years previously he had had a severe attack of nasal catarrh, and that he was subject to colds in the head. My own opinion, which was shared by Dr. Wilkinson and the patient, was that the prompt relief was a consequence of the application of antiseptics to the nasal mucous membrane, where toxines were being manufactured and through which they were being absorbed in quantity sufficient to produce the fever and its associated symptoms.

On July 3rd, 1894, I was consulted by another medical practitioner, who practised in a healthy seaside town, under conditions apparently thoroughly favourable. The town was a favourite health resort, and his house, a very good one, was situated in one of its best parts. He was very anxious about his health. Every day about half an hour after breakfast he expectorated with some difficulty a little mucus, after which he was attacked by rigors that recurred daily and almost with the regularity of ague, to which he compared them. He had continued his professional work, though with much discomfort, while his axillary temperature was often as high as 103° F. The persistence of the condition led him to fear tuberculosis. I examined him with great care. The heart, lungs, and other organs were healthy to physical signs, and, indeed, the only discoverable lesion was a catarrhal condition of the mucous membrane of the left nostril. Under the belief that this lesion might be the cause of his feverishness I urged him to use freely and frequently a snuff composed of equal parts of boric acid and subnitrate of bismuth, and to gargle and, if necessary, to irrigate the nostril well with a strong solution of liquor sodæ chlorinatæ. A few months later I had occasion to go to his town to visit a patient with him, when, in reply to my inquiry, he told me that the fever disappeared at once on the employment of the local disinfectants and had never returned.

On April 9th, 1894, I saw another of my professional brethren in consultation with Dr. Twyford of St. Helens. In June, 1893, or ten months previously, he had had what was thought at the time to be typhoid fever, from which he had never recovered. Dr. Twyford was, however, of opinion that the illness, whatever it was from which he suffered in June, 1893, was the same as that from which he was suffering when I saw him. It was characterised by a rise of temperature every evening for many successive days, each rise being preceded by slight shivering and occasionally by a severe rigor. There had been such a rigor about ten days previously. He had lost three stones in weight. There was, however, this great peculiarity, that he would have at times several consecutive days free from fever, during which he would pick up strength and begin to put on flesh. At the time of my seeing him, which was at 3.30 P.M., his temperature was 101·4° F.; his pulse was 100; and his respiration 28 while in bed, to which he was then confined. He had been kept awake all the previous night by general pains. There were no cramps. The chest was well developed, the lungs and heart on physical examination were found to be healthy, the rapid respiration and quick pulse being possibly explicable by his condition of feverishness. What could be the cause of this long illness? The only discoverable signs were two or three slightly enlarged and tender glands behind the right sterno-mastoid (which, however, had not excited attention till pressure revealed the fact of tenderness) and some slight post-nasal discomfort which caused occasional hawking. In the hope that a lesion in the posterior nares in lymphatic connexion with the tender glands might be the cause of the illness I suggested the use of boric acid as a snuff and the irrigation of the nostrils with a warm solution of the same substance, and also that the nasal cavities should be thoroughly explored. The exploration was made shortly afterwards by a gentleman well skilled in such examinations, but as it was done at the patient's own house, with the disadvantage of defective illumination, nothing was then discovered. Being thus far disappointed in my expectation that a lesion would be detected at the back of the nostrils in lymphatic connexion with the irritated glands I subsequently wrote recommending that at any rate the glands themselves should be treated, while the antiseptic irrigation of the nostrils was persevered with. My advice was that a weak solution of carbolic acid should be injected into the loose cervical cellular tissue all around these glands. I had had injections of carbolic acid made into enlarged glands without any ill result beyond the pain at the moment, and even this can always be prevented by the previous application of a little ice and salt to the surface or by producing local cold in some other way. As I was unable, however, to promise that relief would follow it was not unreasonable that this treatment was declined. On July 12th, 1894, I received a letter from Dr. Twyford, from which I will quote a few lines: "He has now been ill for more than thirteen months, during eight of which he has been so ill as not to be able even to see a patient. Under these circumstances I advised him to go to London and see Dr. ——. I enclose you a copy of his letter." Two of the most distinguished metropolitan physicians were consulted. The conclusions come to were that there was nothing to justify the term leukæmia, there being no increase in the number of the white corpuscles; that there was no anæmia, the blood containing at least 90 per cent. of both corpuscles and hæmoglobin; that there seemed nothing in the past with which the pyrexia and

Digitized by Google

general state could be associated; that the enlargement of the lymphatic glands was curious, but was less significant than it had been from its having lessened; and, finally, that it seemed either a case of one of the untypical forms of tuberculosis or of a chronic constitutional disease allied to lymphadenoma, of which there was at present no definite knowledge. The second gentleman concurred in the view expressed above, with the additional suggestion that the symptoms might be due to some toxic influence possibly left behind by drain poisoning, from which the patient feared that he had originally suffered. A sea voyage and prolonged rest were recommended, together with an alterative and tonic medicinal treatment. It was further concluded that any definitely unfavourable prognosis was unjustifiable, while at the same time the obscurity of the nature of the case precluded any very positive cheerfulness. I only became aware of these opinions some time after they were formed. This was about thirteen months after the commencement of the illness, and nearly three months after I had first seen the patient. The opinions were valuable as precluding any but a rare and obscure form of fever, but they did not seem to consider the possibility of such a cause as I had suggested and had tried by the application of local disinfectants to combat—viz., a lesion at or behind the posterior nares in lymphatic connexion with the enlarged cervical glands, and serving both as a manufactory of poisons and an open door through which they could be introduced into the system. Before long, however, a new fact was observed which gave additional significance to this suggestion and afforded hope, to me at any rate, of a speedy cure. The patient paid a visit to Aberdeen and submitted himself to the examination of Dr. MacKenzie Booth, who discovered and removed a small superficial lamina of necrosed bone beneath the mucous membrane of the posterior nares. Immediately after this there was a subsidence of the fever for over three weeks, an increase of nine pounds in weight, and a feeling of health such as had not been experienced at any time since the illness commenced. I did not see this piece of bone, as I was absent for a prolonged holiday, and only heard of the fact on my return. Unhappily, the intermission was not of very long duration. At the end of the three weeks or thereabouts the favourable anticipations which I had expressed on hearing of what had been done were falsified by a return of all the old symptoms. I still urged the employment of the local disinfectants, but there was apparently no advantageous result either from them or from general treatment of various kinds which I suggested as a supplement to this. Now, also, the lymphatic glands on both sides of the neck became greatly enlarged, indicating, as I thought, that the lesion may have extended across the middle line; and a further careful examination by Dr. Hunt, on this occasion at his own house and with good illumination, led to the discovery and loosening of another piece of necrosed bone close to the site of the previous piece. Though it could be felt with the probe to be loose it could not be detached. Before the patient had reached the bottom of the street, however, he coughed it out into his mouth, and at once sent it to Dr. Hunt, who brought it to me. It was a very small bit, but distinctly winged, showing that it extended on either side across the middle line; and thus the enlarged chain of lymphatic glands on *both* sides of the neck was easily understood. Now I fully believed and told him that the trouble was probably over, and that complete health would soon follow. In a letter received immediately after this he hopes sincerely that my "very favourable prognosis will turn out correct," and goes on to say: "Since I saw Dr. Hunt and had the piece of bone removed I have felt decidedly better." This was on Nov. 12th, 1894. Again, however, every one was doomed to be disappointed, the intermission was shorter than before, and the health seemed to become more seriously broken than ever; so much so that again and again the propriety of abandoning hope of ever being able to practise again was entertained. This, however, I strenuously and steadily opposed, insisting still on the likelihood of recovery. Previously to this date of Nov. 12th I had written to ask to be supplied with a little of the nasal secretion, for I felt that there was wanting one important link in the chain of evidence which, in my opinion, connected the symptoms with a lesion of a special kind at or behind the posterior nares—viz., a lesion which served as the breeding ground of poison-producing microbes. That link was the demonstration of the microbes themselves, and I hoped, if I could procure the nasal secretion, to be able to obtain a pure culture of these, and determine experimentally their fever-producing qualities. And this is the proper place to state that not once or twice, but over and over again, I had insisted on the following as the only adequate explanation of the variations of temperature which the patient exhibited. His charts were forwarded to me from time to time, and the explanation to which I have referred was that microbes were bred in the hitherto undiscovered and unremoved ulcerated surface; that they generated toxines, which, being introduced into the patient's system, poisoned him; that the toxines at length became strong enough and sufficient in amount to poison, or at least to lessen the activity of, themselves; and that during this period of suspended activity the febrile temperature declined, and some slight approach to restored energy was made. Please look at this temperature-chart.[1] It consists of a very long series of waves extending, as you see, over nearly two years, many of the fever periods lasting eight days, with intervals of entire or partial freedom from fever of four or five days. Did anyone ever see a fever chart of this character extending over such a length of time that was explicable on any other supposition? I show you here another, resembling it both in type and time of duration. It is that of a patient whose prolonged and nearly fatal illness was due to a local lesion in the posterior nares which disappeared when it was effectually treated. The case is one of the series to which I have alluded, and was published some months ago. In the present case I had not the advantage of observing the temperature till some time after my first visit to him, and hence on that occasion gave an alternative diagnosis either of poisoning through a local lesion or of an abnormal form of general tuberculosis, but as soon as I did see it my opinion was formed, and never for a moment varied. Still, the demonstration was not forthcoming, and I was disappointed to be informed in a letter of Nov. 6th that there was absolutely no nasal secretion to send me. As I have said, the fever returned some time after the removal of the second piece of bone, and after a period of considerable anxiety the suggestion was made that he should consult another gentleman in London eminent in the departments of laryngology and rhinology. I was not aware of this at the time, happening to be from Liverpool when he called. He saw the gentleman, and he in his turn recommended that Mr. Victor Horsley should be consulted with the view to a digital examination while the patient was under an anæsthetic and to a radical operation if necessary. The examination was made, an operation carried out, and on the following morning I received in Liverpool a letter containing the following very joyful announcement: "Dear Dr. Carter,—I hasten to let you know that Mr. Horsley operated on my husband this afternoon, and found a piece of dead bone with an ulcer behind, somewhere at the back of the posterior nares. The sphenoid was all right." The latter statement was made in consequence of a suggestion from the gentleman who had first been consulted that the symptoms were only explicable on the hypothesis of pus being pent up in the sphenoidal sinuses, which should therefore be opened and evacuated. This suggestion, when it was communicated to me, caused me so much alarm that I instantly wrote to the patient and expressed my very serious doubts as to the necessity of so formidable an operation, pointing out to him that he had never had cephalic symptoms, which I thought must certainly have been prominent if pus, as was suggested, had been pent up in the sphenoidal sinuses for a prolonged time; that the hypothesis was not necessary in order to account for his symptoms; and that no operation should be performed that was not absolutely necessary. After stating my objections to the necessity of such a hypothesis as had been framed I went on to say: "If, however, opening up the sinuses can be effected without any risk, and if thus all the parts can be more effectually antisepticised, I should say by all means have it done, for what you undoubtedly want is something that will put a stop to the necrotic process that is going on, as evidenced by the casting off of two bits of bone, and something that will purify and keep pure the parts from which these bits of bone are thrown off." The day after I wrote the letter from which I have now quoted the patient called upon me on his way up to London. The immediate result you have heard. It is a further proof, if proof were necessary, of the splendid practical surgical skill of Mr. Horsley, and of his combined boldness and conservatism. Opening into the sinuses was not

[1] The lecture was illustrated by the exhibition of temperature charts.

Digitized by Google

necessary, and hence was not done. The exact nature and extent of the operation may possibly be some day recorded by Mr. Horsley himself. All that I am concerned about here is its splendid practical results. From the day of its performance (more than two months ago) to the present moment all fever has ceased. As soon as the necessary period of rest had passed and food could be taken the body weight increased for some weeks at the rate of half a pound a day, and the patient is now as well as he has ever been in his life, and for a considerable time has been able to resume without fatigue the duties of an arduous practice. The congratulations which for the third time I ventured to offer immediately after the operation have happily been justified by the result, and the whole case presents, I think, one of the most striking examples of a supposed inexplicable fever, proving to be both explicable and removable when a source of local septic infection was once got at and removed.

The last case that I shall bring to your notice differs from those previously narrated in the fact of its having arisen in the course of a surgical affection. On Feb. 15th, 1895, I was requested to see with my friend and colleague, Mr. Robert Jones, and Dr. Chisholm of Woolton, a man aged twenty-three years, a resident of that place. This patient had always been perfectly healthy up to about a year previously, when he met with a very severe accident, which, besides bruising him generally, caused compound fracture of the bones of the right leg. As the result of this he became subject to great, and what was feared would prove a permanent, deformity, a circumstance of such serious importance to a young man that the advice of Mr. Jones was sought as to whether anything could be done to remedy it. By a series of ingeniously devised and successfully executed operations this deformity was entirely overcome, and all that remained was a very extensive area denuded of skin, which it was proposed to fill up by grafting. For this purpose plastic operation was carried out on Feb. 3rd to supply the place of the destroyed skin. Everything that prudence could suggest seemed to have been devised to ensure the success of this. A room was specially selected on account of its cheerful aspect and freedom from every suspicion of sanitary defect. Two nurses of skill and experience in antiseptic surgery were engaged. For a day or two everything went well. The wound was from the first antisepticised. No hand was allowed to touch it except after thorough cleansing with disinfectant. The bowels were carefully attended to, and every hope entertained of success, when a slight feeling of malaise on the evening of the 3rd, accompanied by a moderate rise of temperature, began to excite uneasiness. The wound was examined and found to be sweet. Day by day, however, the symptoms were intensified. The temperature rose as high as 104·4° F., the rise being preceded by a feeling of shivering and occasionally by a somewhat severe rigor, and followed by profuse sweating. Emaciation set in and was progressing somewhat rapidly, in spite of a fair amount of judiciously selected nourishment, and the utmost anxiety was felt and expressed on all hands for his condition. Ten days after the commencement of these symptoms, which continued daily and increased rather than diminished in intensity as time went on, I was asked to see him. A very careful examination of all the large organs failed to detect anything that could throw light upon the condition. The heart, lungs, kidneys, and other abdominal organs seemed to be healthy. I examined the nose and could find no evidence of disease in it that might explain the symptoms. I then asked permission to examine the granulating surface. It was carefully exposed by removal of the antiseptic dressings and certainly at first sight looked very healthy. After a thorough cleansing of my hands in a weak solution of perchloride of mercury I went round its edge. On almost every portion of this there was the white film creeping in by which the gap was being filled in, and the skin to a gentle touch seemed firm and adherent. From one minute spot, however, the white film was absent, and here the skin, instead of adhering to the subjacent tissues, felt slightly loose. On pressing over this minute bit of skin a single drop of pus was squeezed out. A cleansed probe introduced at the spot penetrated for a few lines. I ventured to express the belief that absorption of septic material through this very small spot, that seemed to have escaped the reach of the antiseptics, was sufficient to account for all the symptoms, and with the view of putting this to the test we agreed to instruct the nurses to inject a weak solution of perchloride of mercury by means of a small syringe, whose fine nozzle was to be introduced under the skin at the point where it had admitted the probe, but to make no other alteration in treatment, which had consisted mainly of the administration of quinine. The moment this was done the temperature fell to normal and never again rose. The patient has for some time been at the seaside convalescent.

THE OPERATION FOR THE RADICAL CURE OF HYDROCELE BY EXCISION OF THE SAC, ILLUSTRATED BY A SERIES OF CASES.[1]

BY C. B. LOCKWOOD, F.R.C.S. Eng.,
ASSISTANT SURGEON TO ST. BARTHOLOMEW'S HOSPITAL; SURGEON TO THE GREAT NORTHERN CENTRAL HOSPITAL.

I VENTURE to introduce this subject because it has not yet been discussed by the Medical Society of London, also because the operation for the cure of hydrocele by excision of the sac does not seem to be so well known as it undoubtedly deserves to be. During the last ten years (1885 to 1894 inclusive) one hundred and thirteen cases of hydrocele were treated by operation in the wards of St. Bartholomew's Hospital,[2] only thirteen of these are said to have been treated by incision and excision of the sac wall. Forty-eight of the remainder were injected with iodine; forty-five are said to have had radical cure done; and, lastly, seven were treated with setons. With the help of Mr. E. G. B. Adams, to whom I am under a great obligation, I have examined the notes of these cases. There is no doubt but that the forty-five who are said to have been treated by "radical cure" had the hydrocele injected with iodine, black wash, or carbolic acid, the last two being used in a very few instances. Hydrocele is such a common disease and causes so much mental and physical inconvenience that some good reason must exist to explain why only 110 cases passed through the wards of a great hospital in a decade. I myself am inclined to attribute it in a measure to the uncertainty of injection, and to the fact that besides being uncertain it is very painful. My own observations have long caused me to look askance at this procedure. That it often failed there could be no doubt, but I did not know in what proportion; that it was exceedingly painful was also evident; and that epididymitis and orchitis were not infrequent consequences could not be denied. Now, whatever the patients themselves might think, it seems evident that one would be chary in recommending an operation which, after much pain and discomfort, might not succeed, or which might leave the patient with an additional disease. With regard to the question of failure I was not astonished to read in Mr. Jacobson's recent work that he estimates the failures after injection at from 8 to 10 per cent.[3] The exhaustive labours of this writer and his temperate and judicial attitude give great weight to this statement.

With the help of Mr. Adams I have examined the notes of the cases of hydrocele in the wards of St. Bartholomew's Hospital during the last ten years. We have abstracted the notes of seventy-four patients who had been treated by injection, the total number of injections being ninety-three. In six of these the ultimate result was doubtful; they were not cured when last seen.[4] In twenty-four the injection had undoubtedly failed. The above seems a very high proportion of failures. It is to be remembered, however, that many of the cases may have been admitted into the hospital because they were known to be intractable. Nevertheless, they deepen my own distrust of the so-called cure by injection. The history of these twenty-four failures is remarkable: ten failed after one injection, eleven had two injections, one had three injections, and two had four. In those which had two, three, or four injections the result is in many cases unknown, but some were ultimately treated by excision of the sac. Of the two cases which were tapped four times, one, a

[4] One has since written to say he considers himself well, the swelling having "gone right down." I am greatly obliged to Mr. Maxwell for much help in obtaining the addresses of these cases.

Digitized by Google

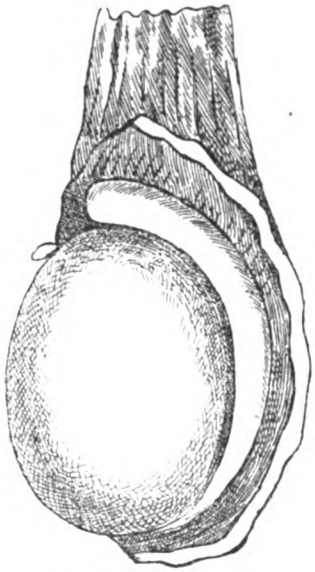
medical man, tells me that he now, after much suffering, has a spermatocele; the other seems to have been cured by carbolic acid after three injections with iodine. The patient who was injected three times had a most remarkable career. His hydrocele, which is said to have followed a blow, was tapped, thrice injected with iodine, twice incised and drained, and, finally, laid open, painted with liquor iodi, and packed with iodoform gauze. There is reason to believe that this was successful. The case was described by Mr. Willett in the discussion before the Royal Medical and Chirurgical Society.[5] It may be noticed that excision of the parietal layer of the tunica vaginalis was not performed.

Out of the twenty-four operations which I have now done for the cure of passive hydrocele, two had previously been injected with iodine and relapsed. When the tunica vaginalis was opened no adhesions were found, but in one the testicle was chronically inflamed, although the injection had been done eighteen months before the operation, and the other has still a nodular condition of the testis and epididymis. These two cases of relapse are included in the twenty-four which have just been mentioned. Thus the chances of relapse after an attempt at cure by injection are very considerable; rather over 32 per cent. according to the statistics of St. Bartholomew's Hospital. Evidently the operation is not one to be recommended with confidence. With regard to the painfulness of it, I feel sure (in spite of the enthusiastic statements of some surgeons) that it is considerable. Putting aside what I myself have seen, it is clear from the notes that, although cocaine was freely used, pain which needed morphia for its alleviation was quite common and occasionally was so severe as to make the patient sick. It seems unreasonable to suppose that a violent irritant can be applied to the surface of a sensitive organ like the testicle without causing considerable pain. Two of the patients upon whom I operated for radical cure of hydrocele by excision of the sac had, as I have just said, previously been operated upon by the injection of iodine. They were most emphatic that the excision was much less painful, and was, indeed, comparatively comfortable compared with injection. Nor am I convinced that injection with carbolic acid has the advantages which some have claimed for it. I can only find that five patients were injected with carbolic acid in the wards of St. Bartholomew's Hospital in the ten years 1885 to 1894 inclusive. They received six injections. Two of these injections failed. In one case a second injection with carbolic acid seems to have succeeded, but it is said that the epididymis was much enlarged. In a second case an unsuccessful injection with carbolic acid was followed by an unsuccessful injection with iodine. Finally, the parietal layer of the tunica vaginalis was excised. The other three patients were probably cured by one injection with carbolic acid. One is said to have suffered pain. This might be expected. Experiments upon animals incline me to think that carbolic acid is a violent remedy, and no one can deny that the testicle is a sensitive organ.

I do not propose to discuss all the alternatives to injection. A case has been mentioned in which incision and drainage failed twice. A diverticulum of the tunica vaginalis may, it is said, have been the cause of these persistent failures. Setons were inserted seven times into the hydroceles of infants and young boys. One of these is known to have relapsed and had a seton inserted for the second time. Partial excision of the parietal layer of the tunica vaginalis has also been tried. In one of these it is said that "so much of the sac was removed that it was difficult to bring the remainder together." The wound was drained for fourteen days, but nevertheless, before the man left "a small fluid tumour had already returned." Incision of the tunica vaginalis and after-packing with lint and subsequent sepsis and suppuration is a repugnant procedure. Excision of the sac, on the other hand, may be rendered an aseptic process, and seems to me to afford an excellent prospect of success. It seems reasonable to suppose that the removal of about nine-tenths of the diseased secreting membrane, and the exposure of what is left to the loose cellular tissue of the scrotum, could hardly be followed by a reaccumulation of the hydrocele fluid. The results of the operation will, I think, go far to show that this assumption is correct. And here it is to be said that the title of this paper is not strictly applicable to the operation performed upon ordinary hydrocele of the tunica vaginalis. For the cure of these only the parietal layer of the tunica vaginalis has been excised (Fig. 1), but in encysted hydrocele the whole sac is cut away. I have now excised the whole of the parietal layer of the tunica vaginalis twenty-five times. All of these were done for the cure of hydrocele, with the exception of one which was done for hæmatocele. No attempt whatever was made to select the cases. The youngest was sixteen years old, the oldest sixty-eight. Some could hardly be considered good subjects for an operation. A man aged forty-one had been a heavy drinker. His face was covered with acne rosacea. He had a high-tension pulse and probably some aortic stenosis. His urine contained a trace of albumen. He took ether well and suffered no apparent harm from the operation. A man aged sixty-three who had acne admitted that he drank; another, who was a plumber, suffered from lead poisoning; several had chronic bronchitis. This is a very objectionable complication, on account of the anæsthetic. However, by choosing the warm months of the year for the operation and by skilful administration of the anæsthetic this complication need cause little anxiety. In several cases the hydrocele was accompanied by other affections. In one a hydrocele on the right side and a varicocele on the left were operated upon at the same time. In another both sides were operated upon at the same time, the hydrocele being double. In another case the presence of an acquired hernia upon the same side as the hydrocele made no difference. A man who had a hydrocele and organic strictures of the urethra was operated upon first for the cure of the hydrocele, and a week later for the cure of the strictures. The last operation was followed by orchitis. In one case the hydrocele was bilocular. The testicle was surrounded by an ordinary hydrocele of the tunica vaginalis. A second large sac, full of about half a pint of clear yellow fluid, lay above the head of the epididymis. Both sacs were treated in the usual manner, the upper one being entirely removed. The operation was performed for various reasons—in some because of the size and weight of the hydrocele; in others for pain and discomfort, especially whilst riding upon horseback. Some were done to enable the patients to enter the army or other public services. One was done to enable the patient to wear a truss for a hernia which was unsuitable for radical cure. Some were performed because the patients were weary of being tapped; one man had been tapped twenty-four times. One patient was alarmed because his hydrocele had been burst at football. This accident had not brought about a cure, as happened to a man I saw under Mr. Butlin's care, and of whom it is stated that his hydrocele had been burst by the wheel of a wagon passing over it. Another reason might, I think, influence the decision. At various times I have dissected a number of hydroceles. In the large ones of long duration the testicle had become flattened out and wasted, and apparently spoilt. In some of the operative cases [the gland was considerably altered, the epididymis having become separated from the body of the testis.

Before operating for the radical cure of hydrocele by excision of the sac it is, as a rule, advisable to tap once to ascertain the condition of the testis. It would be disappointing to find a gumma, or a mass of tubercle, or even a malignant growth. Inasmuch as the fluid in a hydrocele is quite thin, like water, a very small trochar and cannula suffice for the tapping. A cannula of 2 mm. diameter is quite large enough. The instrument usually figured in textbooks is a relic of mediæval surgery. Strange to say, one of those upon whom I intended to operate underwent spontaneous cure. A man aged sixty-five came in January, 1894, with a hydrocele of two years' duration. It had been tapped five times. He had bronchitis, so I tapped it again and told him to come in June to be cured. He returned in June with no trace of hydrocele, and said that after the tapping it had rapidly refilled and then got quickly well. He remains quite well of his hydrocele at this date (October, 1895). He attributed his cure to some spirits of camphor which he was taking. I also find it stated in the notes that a youth aged seventeen, who was under the care of Mr. Thomas Smith, had undergone spontaneous cure of his hydrocele. He had had it three years, and it had been injected once with iodine, but had relapsed. No reason could be assigned for the cure. This event is, of course, too rare to have any practical bearing upon the question of operation.

The operation of excision of the parietal layer of the tunica vaginalis is exceedingly simple. An incision is made the whole length of the long axis of the hydrocele The sac is exposed and separated from the scrotum until



[5] THE LANCET, March 3rd, 1888.

Digitized by Google

the spermatic vessels are almost in view. It matters little if the testicle is entirely withdrawn from the scrotum. A puncture is made to let out the hydrocele fluid. This small opening is enlarged to admit the finger to ascertain the position of the testicle, epididymis, and vas deferens. Occasionally the vas is upon the front of the sac, having been displaced. The testis, too, is sometimes in front, as in one of my cases. As a rule this point will have cleared up before the operation is begun; but when the sac is thick the shadow of the testis cannot be seen. The finger in the sac also makes out the exact limits of the epididymis and of the testicle. In big old hydroceles these organs are flattened out and sometimes pulled apart. In one of the cases upon which I operated this had happened, and the epididymis, separated from the testis, lay almost in front of the sac.

These points having been cleared up the whole of the parietal layer of the tunica vaginalis is cut away to within a quarter of an inch of the testicle and epididymis, so that these organs are left in the condition shown in the accompanying sketch. (Fig. 1.) Much misconception seems to

FIG. 1.

Showing how much of the tunica vaginalis is removed for the cure of hydrocele.

exist as to the quantity of tunica vaginalis which is taken away. I am continually asked whether the visceral layer is dissected off the testis and epididymis. Sometimes in very big hydroceles the tunica vaginalis runs up the front of the spermatic cord. This prolongation must be thoroughly removed. The arrest of hæmorrhage is of the utmost importance in this, as in other operations upon the scrotum. A hæmatoma easily forms in the scrotum and detracts considerably from the comfort of the patient and from the success of the operation. In one of my cases no vessel required ligature, but as a rule eight or twelve have to be secured with fine twisted silk. As a further provision against a hæmatoma a large drainage-tube (½ in. diameter) is laid along the depths of the wound and brought out at its upper angle. The rest of the skin incision is closed with fishing-gut sutures placed about a third of an inch apart. Trouble expended in obtaining accurate apposition of the wound is well repaid. The skin of the scrotum heals with great rapidity, and the union becomes quite strong in a week. It may be observed that no caustic is applied to the visceral layer of the tunica vaginalis, which is, of course, left behind. I do not think such applications are required, and they would increase the pain and also cause orchitis. As I have said, twenty-four hydroceles were treated in this way. In addition a hæmatocele was met with, and received the same treatment. After all the blood and clot had been taken away the whole of the parietal layer of the tunica vaginalis was excised. The after-treatment was the same as that of the hydrocele cases, and will be described presently. Repair was rapid, and the after-result left nothing to be desired.

It would not, in my opinion, be justifiable to perform these operations for the cure of hydrocele without stringent aseptic precautions. Inasmuch as surgeons differ as to what these should be perhaps I may be allowed to say very briefly what was done in all of these operations. The aseptic precautions pertain mainly to the preparation of the patient, of the surgeon and his assistant, and of the instruments and materials. The evening before the operation the patient is thoroughly shaved and has a hot bath with abundant soaping and scrubbing. The skin having been cleansed as far as can be done by soaping and scrubbing, it is further prepared for disinfection by extracting its fatty matter with ether or turpentine. It is disinfected by being washed for two minutes with a 1 in 500 solution of biniodide of mercury in rectified or methylated spirit. This is washed away with biniodide of mercury lotion (1 in 2000), and the skin is covered with a covering of carbolic gauze wet with the same lotion. It is, I think, advisable to add some glycerine to this lotion to help to keep the covering moist and assist the chemical to penetrate the skin. It is usual, also, to give a mild purge the night before the operation. These precautions are used for hospital patients; but for others less drastic measures usually suffice. The hands of the surgeon and of his assistants are apt to be a source of infection. After cutting the nails short, and scrubbing for three minutes with soap and hot water, we disinfect them by soaking for two minutes in the same solution of spirit and biniodide of mercury (1 in 500) as was used for the patient's skin. This has hardly any harmful effect even upon delicate skin. My hands are quite unable to bear the strong solutions of carbolic acid which some surgeons recommend. Very few instruments are required; a knife, a pair of scissors, a needle, and a few pairs of pressure forceps are all that is necessary. These, together with the drainage-tube, are sterilised by boiling for a quarter of an hour. Fine twisted silk (No. 0 size) is used to ligature bleeding vessels, and fishing gut for closing the incision. These are also sterilised by boiling, and together with the instruments are afterwards kept in freshly made carbolic solution (1 in 40). After the patient has been anæsthetised the field of operation is prepared by removing the protective dressing and thoroughly wrapping up the penis in carbolic gauze which has been soaked in binionide of mercury lotion (1 in 2000). This "phallic shield" is of the greatest importance in this and other operations about the genital organs, especially in operations for varicocele and for the radical cure of hernia. The area of operation is surrounded with towels sterilised by boiling or steaming for half an hour, and kept wet with 1 in 40 carbolic lotion. One of these towels is passed across the thighs and under the hydrocele to support it. Before making the incision the skin receives a final swabbing with spirit and biniodide, and is then sluiced with 1 in 2000 biniodide of mercury lotion, which is used throughout the operation. I use sponges prepared by the sulphurous acid method.[6] The wound is dressed as follows: After a thorough dusting with iodoform crystals the scrotum is covered with a layer of 5 per cent. carbolic gauze soaked in biniodide of mercury lotion (1 in 2000). This is covered with alembroth wool and an outside dressing applied. The outside dressing is the usual eight-fold layer of carbolic gauze with a covering of jaconet. It is accurately cut to pattern and fitted with great care. (Fig. 2.) It is triangular, with an aperture near the base for the penis to pass through. To the apex of the triangle two strong bands are fixed. When the dressing is in position these bands fix its apex against the perineum and are carried round the thighs to meet the pelvic band in front. This is a similar band of soft material which is fastened to the other angles of the dressing. They secure it firmly in position by being carried round the pelvis. The straps are best made of stout bandage or of webbing. After they have been pulled tight a little extra alembroth wool may be stuffed beneath the dressing to exclude air and make some pressure upon the scrotum. I have used this dressing now for a great number of cases of radical cure of hydrocele and varicocele, for castration, and other operations on the scrotum. I have no doubt but that other surgeons have bethought themselves of such a simple device. It is quite safe and very easy to adjust. The patients find it most comfortable, and are able to turn about in bed and if necessary get up with it on. It enables us to dispense with bandages, always

Digitized by Google

difficult to apply in this region, and notoriously insecure. The after-treatment of these cases is simple and uniform. After the anæsthetic has passed off any light diet may be given, and the minor indulgences need not be stopped. The dressing is taken off at the end of forty-eight hours for the removal of the drainage-tube. This is done with the same precautions as those used for the operation. On the seventh or eighth day the dressing is finally removed and a suspensory bandage of linen applied. The patient now gets up to lie on a couch, and is able to begin work again within a fortnight.

The immediate results of excision of the parietal layer of the tunica vaginalis seem to leave little to be desired. The

FIG. 2.

asepsis, which is so essential to safety, seems easy to secure. Only one of the cases had subacute suppuration, which was by no means severe. Owing to his physical conformation urine escaped several times into the dressing. We were aware of the likelihood of this accident and endeavoured to shut off the wound with iodoform, collodion, and so forth. The man, however, was negligent and unintelligent, and did little to aid our efforts. Seven months after the operation he was quite cured, and, except for the scar, it would be impossible to find anything abnormal.

A striking feature of these cases has been the absence of orchitis. The case which has just been mentioned is supposed to have had some orchitis, and a youth was found to have some orchitis at the operation; but I am not aware that any of the others had it. Indeed, the testicle seems to be surprisingly tolerant of any reasonable amount of handling. With the above exception the after-course of these twenty-five cases has been quite monotonous. The drainage-tube was withdrawn in from forty to forty-eight hours, and the stitches removed six days later. By this time the wound was healed and merely required protecting with a little wool. After the removal of the stitches the patient was provided with a linen suspender, and got up to lie upon a couch. He was usually fit for work within a fortnight. The patients themselves greatly appreciate the relief which the operation affords, and have been profuse in their expressions of gratitude.

I think the foregoing shows that when excision of the parietal tunica vaginalis is done with strict aseptic precautions the immediate results of the operation leave little to be desired. The greatest pains have also been taken to ascertain the after-results. It may be noted that we have to deal with twenty-three patients upon whom excision of the parietal layer of the tunica vaginalis had been practised twenty-four times, the hydrocele having been on both sides in one instance.

Everyone will acknowledge the extreme difficulty of tracing cases in London. I have, however, succeeded in following up sixteen of these patients. Fourteen have been seen by myself or other surgeons, and are all cured, including the case of double hydrocele. Two have written to say they are cured. One of these patients has been well for close upon two years, two over eighteen months, and none less than three months. To these may be added another case, that of a man upon whom my friend and colleague, Mr. Bowlby, performed exactly the same operation. It was done on Nov. 7th, 1894, and the patient is now quite well (Oct. 4th, 1895).[7] Thus I have not yet met with a relapse after complete aseptic excision of the parietal layer of the tunica vaginalis. I am fully aware that relapses have been described;[8] but it is probable that those cases were not operated upon in the same way as those dealt with in this communication.

Examination of cases which have been operated upon shows that the scar of the incision is hardly visible. The testicle slips about quite freely within the scrotum. The gland in most cases is larger than its fellow, but quite soft and painless. I have observed this slight enlargement in cases which have been cured by iodine. It has probably nothing to do with the operation, but is related in some way to the hydrocele.

It is not intended upon this occasion to touch upon the pathology of hydrocele. Doubtless more than one cause has to be considered. Dr. Kanthack, pathologist to St. Bartholomew's Hospital, kindly examined the tunica vaginalis removed from two cases of passive hydrocele. He found in the thickened membrane evidence of chronic inflammation. At my suggestion tubercle bacilli were sought for, but none were found. The mammillæ scattered over the thickened tunica vaginalis in cases of hydrocele are very suggestive of tubercle.

Inasmuch as they have the closest relationship to the cure of ordinary passive hydrocele, I propose to mention very briefly a case of operation for congenital hydrocele and another one in which there was hydrocele associated with hernia. The first was that of a youth who had a congenital hydrocele of the right side. The fluid in the sac could be reduced into the abdomen. An incision was made over the inguinal canal, and a long, narrow peritoneal tube was found leading into the general peritoneal cavity. This was separated from the spermatic cord and divided, and the stump fastened beneath the arching fibres of the internal oblique and transversalis.[9] The inguinal canal did not require repairing, but the external abdominal ring was closed to its proper size with the usual silk sutures. No drain was inserted, and the wound healed by first intention. It will have been noticed that the tunica vaginalis was not touched, but was left alone, as in an ordinary case of congenital hernia. I now regret that I did not excise the parietal

[7] The patient, together with fourteen others, was shown to the Medical Society at the meeting.

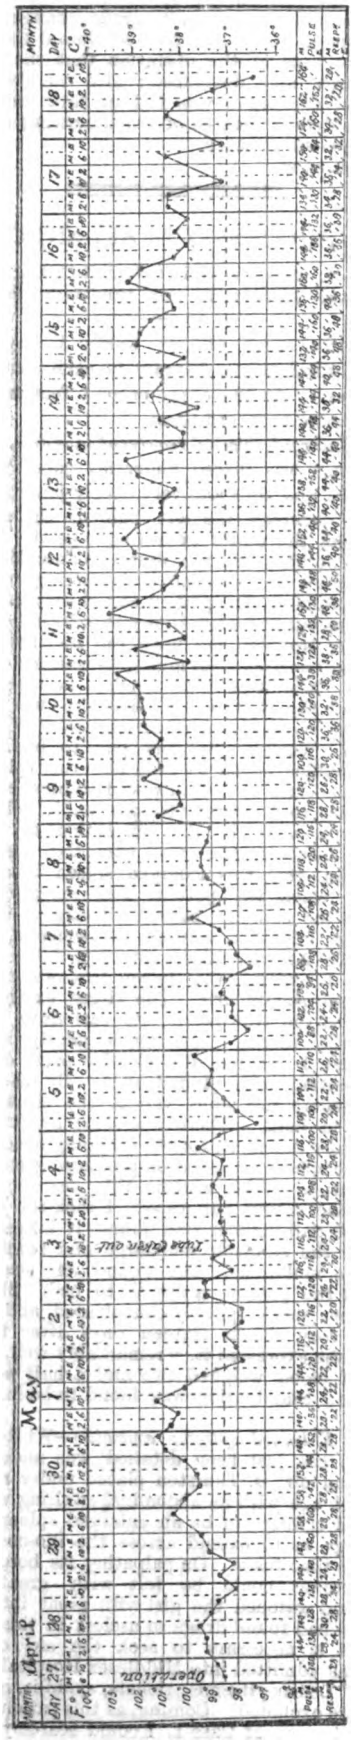
Digitized by Google

layer, because five months after the operation there was some swelling about the testicle and perhaps a little fluid in the tunica vaginalis. The removal of the parietal layer of the tunica vaginalis in a case of this kind would be a very slight addition to the operation. In future I shall certainly take it away. Indeed, in another case of hydrocele which was associated with hernia this proceeding was adopted. The hydrocele seemed like one of the ordinary kind, but the cord was thickened, and it was thought that there was a narrow and patent processus vaginalis plugged with a strip of omentum. The operation which I usually perform for the radical cure of hernia was done.[10] The peritoneal canal was occluded and the inguinal canal repaired. The lower part of the sac was laid open and in great part removed. It was difficult to make out its exact relation to the testicle, but it closely enveloped it and was, I thought, composed of the upper but not the lower part of the tunica vaginalis. This wound was not drained, and healed by first intention. Mr. Withers informs me that the hydrocele is cured. It is hardly necessary to point out that the above was a chronic hydrocele of a hernial sac. I have many times met with acute hydrocele in strangulated hernia, but in these it seems unnecessary to excise any of the tunica vaginalis. I have never known the effusion to return and persist after it has been evacuated.

Encysted hydroceles of the spermatic cord are also most suitable for excision of the sac. Apart from cases of hernia, I have not myself had an opportunity of dissecting out the sac of an encysted hydrocele of the cord. It is, however, a simple and safe procedure and much to be preferred to injections. From the nature of the case a relapse could not occur. Two patients who were operated upon by other surgeons write to say they are cured.



A CASE OF EXTRA-UTERINE FŒTATION; OPERATION NEAR FULL TERM; CHILD LIVING; DEATH OF MOTHER THREE WEEKS AFTER DELIVERY.

BY MONTAGU HANDFIELD-JONES, M.D. LOND.,
OBSTETRIC PHYSICIAN TO, AND LECTURER ON MIDWIFERY AND DISEASES OF WOMEN AT, ST. MARY'S HOSPITAL.

THE patient was a woman aged twenty-six years, married seven years previously, and had one child (a boy). This confinement took place twelve months after marriage, was quite normal, and the child, who was healthy, lived twelve months. There had been no miscarriage. Menstruation commenced at the age of thirteen, had always been regular, not very free in amount, and without pain. The patient had been quite well both before and since her confinement, and had menstruated regularly till the last week in August, 1891. She saw a little at the end of November, 1891, and again in December, 1891, about the time of her ordinary monthly periods; the flow was scanty, but there was no pain, except with the loss in November. On Nov. 24th, 1891, she commenced to vomit and was sick for two days. During this time she says that she had pain right across her stomach. She took to her bed and sent for Mr. Archer Wood of Dulwich. Mr. Wood found her markedly anæmic and very much prostrated. On examining the abdomen he found a hard, rounded lump rising above the right Poupart's ligament and apparently springing from out of the true pelvis. The patient complained of a few "pleuritic pains," but these ceased after a few days and improvement took place. A similar attack occurred a week later, and a third after another fortnight's interval, but these two were not so severe as the first attack. After these attacks there was no return of pain, but as the lump did not disappear the patient was not allowed to leave her bed. The lump was first noticed on the right side three days after the first attack of pain. On Dec. 15th Mr. Archer Wood asked me to see the patient in consultation. On this date she was feeling well, free from pain, and anxious to be allowed to leave her bed. There was a slight degree of anæmia. The breasts were suggestive of pregnancy. The abdomen was full, and above the right Poupart's ligament there was a [illegible] a rounded top, firm and solid to palpation, fixed in position, very little tender to the touch, and reaching half-way up to the level of the umbilicus. By vaginal examination the uterus was found pushed over to the left of the middle line and fixed; while to the right and behind there was a firm mass which depressed the vaginal roof on that side and was evidently continuous with the abdominal tumour. The diagnosis pointed clearly to an extra-uterine pregnancy on the right side, and the symptoms suggested the occurrence of rupture with a moderate out-pouring of blood. As the patient was so well it was decided to leave matters alone and watch the further progress of events, the patient meanwhile remaining absolutely in bed. About the middle of January, 1892, Mr. Archer Wood wrote to tell me that all was going on favourably, and that there had not been any further signs of bleeding, but he thought that the tumour was increasing in size. Under these conditions we decided to move the patient into St. Mary's Hospital, so that I might have her under close observation and be able to operate at once if need arose. On Feb. 3rd the patient was admitted to St. Mary's Hospital, and the following notes were taken. On inspection of the abdomen there was found a dome-shaped swelling in the right iliac region which reached above the umbilicus to the height of two inches. The skin was freely movable over the tumour and there was complete dulness on percussion. No movements or adventitious sounds could be detected. The following were the measurements: right anterior superior iliac spine to umbilicus, 5¼ in.; left ditto, 5½ in.; umbilicus to xiphoid cartilage, 5¾ in.; umbilicus to symphysis pubis, 6½ in.; left side (horizontal), spinal column to umbilicus, 12½ in.; right side, ditto, 13¼ in. (over the most prominent part of the tumour). On vaginal examination the body of the uterus was felt pushed over to the left side; the cervix pointed backwards and to the right. The body of the uterus was considerably enlarged, and the right fornix of the vagina was occupied by a hard swelling which seemed to be continuous with the abdominal tumour. The swelling in the right iliac region was not obviously distinct from the uterus. On Feb. 11th the patient said she had had no pain since admission. No movements had been felt, and no sounds had been heard over the tumour. On Feb. 19th the circumference of the body measured over the most prominent part of the tumour 30 in. The following were the measurements: left anterior superior spine to umbilicus, 6½ in.; right ditto, 5¾ in.; umbilicus to xiphoid cartilage, 6½ in.; umbilicus to symphysis pubis, 6¾ in. On the night of the 18th, about 12 o'clock, the patient was awakened by a sharp pain in her right side, which passed from behind forwards through the tumour. She went to sleep in an hour's time, but the pain awakened her at intervals for three or four hours. She did not feel at all sick and felt quite well again in the morning. On Feb. 23rd there was no return of pain. On the anterior abdominal wall on the left side, half-way between the anterior superior iliac spine and the umbilicus, fœtal movements were distinctly felt. On March 10th the measurement round the abdomen was 31½ in. On March 28th the patient said she felt movements every day, but had no pain. The tumour was steadily enlarging upwards and to the right. The urine was acid, contained no albumin, and the specific gravity was 1028. It deposited urates. The measurement around the abdomen equalled 32¼ in. On April 12th the patient was progressing favourably. The girth now equalled 33¾ in. So far no shreds of membrane or decidual cast had been expelled. As by the end of this month the patient would have reached about the 250th day of gestation, it had been decided to operate at that time and not go quite up to full term. On April 27th the abdomen of the patient closely resembled the appearance of an ordinary case of gravidity about the end of the eighth month, except that there was a marked bossing on the right side between the lower ribs and Poupart's ligament. Careful palpation led to the belief that the swelling was caused by the placenta, a view which was found to be correct at the operation. By combined abdominal and vaginal examination the child was felt to be lying obliquely to the vertical axis of the abdomen; the head resting on the brim of the pelvis towards the left side, the back of the fœtus directed forwards, and the breech high up to the right of the middle line. On percussion dulness was found nearly up to the xiphoid cartilage, extending outwards into the right flank, but good resonance was obtained on the left side of the abdomen. Rising about three inches above the level of the symphysis pubis there

[10] THE LANCET, Nov. 25th, 1893.

Digitized by Google

was a rounded swelling which could be differentiated from the fœtal tumour and which was almost certainly the hypertrophied uterus. The vaginal conditions had not markedly changed since the last examination. On this date the patient was moved into the ovariotomy ward, and after chloroform had been administered by Mr. Henry Davis my colleagues Dr. Braxton Hicks and Dr. Gow kindly assisted me in the operation of removing the child by abdominal section. When the abdominal parietes had been divided by a long incision reaching from above the umbilicus to within two and a half inches of the symphysis, the following condition was revealed. Below was the hypertrophied body of the uterus rising some three inches above the brim of the pelvis; above this the smooth and convex surface of the fœtal membranes was seen, overlapping the membranes on the left side, and above were coils of intestine. Having picked the membranes about the centre of the exposed surface and incised them with scissors, several ounces of clear, watery fluid escaped, and then a second bag of membranes came into view. Manifestly the fluid which had escaped was situated between the chorion and amnion. The latter membrane was now incised and a sharp rush of clear amniotic fluid escaped. The fœtus was now lifted out of the abdomen, the cord rapidly tied, and the child handed over to an assistant; a sharp, lusty cry testified to its vitality and vigour. Dr. Braxton Hicks examined the placenta at this stage with me to decide the question of further treatment, but as blood began to well up rapidly from the deep part of the organ it was deemed unadvisable to attempt its removal. As far as we could ascertain the organ was attached low down in the pelvis on the right side over the right iliac fossa, and then spread up over the right flank till it was reflected by the diaphragm and ribs into the right abdominal wall. The umbilical cord was now cut short and dropped back into the sac of the membranes, the intestines were carefully sponged, and the cut edges of the membranes having been gathered up were sutured to the edges of the abdominal incision; finally, the abdominal wound was closed except for two inches at its lower part, where a rubber drainage-tube was passed down into the sac of the membranes. The wound was now dressed in the manner usual after an ovariotomy, and a many-tailed binder having been applied the patient was placed back in bed. The pulse was 140, the respiration 26, and the temperature 98·8° F. The patient had a rapid pulse an hour after the operation, but otherwise showed no marked symptom of shock. The infant was of the female sex, was well nourished, and weighed nearly seven pounds; there was a curious flattening of the left parietal bone, due apparently to pressure of the child's skull against the bony wall of the pelvis. At first the child was unable to take milk from the feeding bottle (owing apparently to some difficulty in sucking) and had to be fed by a catheter passed back through the nose; but in a few weeks' time this trouble had passed and the infant was brought up by hand in the ordinary way. When she left the hospital at the end of three months she was in all respects a well-nourished and well-developed child.

After-history.—The following notes taken by my clerk, Mr. Frank Easton, give a fair view of the patient's progress after the operation. On May 3rd she was very cheerful. The wound was dressed and the tube taken out. The discharge was less sanious and less copious. The temperature kept down and the pulse became slower, being 112, as against 140 just after the operation and 160 two days later. The child was jaundiced, but was getting on well; she was fed by the tube being passed into the stomach. On May 4th the stitches were removed. The bowels were freely relieved. The abdomen was much less distended and was soft and natural. On May 6th the patient slept well and took solid food with a good appetite. She was propped up in bed and did some wool-work. The pulse-rate was 88 in the evening. On May 8th the patient was not so well and was drowsy. The pulse was quicker and the tongue was furred. The cavity of the membranes had greatly shrunk and the anterior surface of the placenta bulged up into the abdominal opening. The discharge was perfectly sweet. On May 11th she was sick twice and still drowsy; some sloughs of membranes were removed through the abdominal wound. The temperature was 102°. The area of dulness over the placental site was diminishing. On May 12th the patient was worse; she disliked her food and looked sallow. From this date she slowly lost flesh and strength, drifted into a typhoid condition, and died on May 18th.

Digitized by Google

Necropsy.—On opening the abdomen the fœtal membranes were found firmly adherent round the abdominal incision, entirely shutting off the peritoneal cavity. Some coils of intestine were adherent around the fœtal sac, but there was no sign of any general peritonitis. The uterus corresponded in size to a three months' gestation, was somewhat displaced to the left, and contained a well-marked decidual membrane, which was detached and loose in the lower zone, but adherent still above. The left ovary and tube were somewhat thickened and matted, but otherwise were normal. The right tube was much elongated and continuous at what was apparently its fimbriated end with the fœtal sac. The right ovary was represented by a small nodular mass situated at the lower part of the fœtal sac. The placenta spread upwards from the pelvis, and the side of the uterus was adherent over the whole right iliac fossa, then passed upwards over the region of the right kidney, and then passed forwards on to the right side of the abdominal wall. The aspect of the peritoneum at the site of attachment was so altered that it was difficult to trace its relations. Numerous vessels passed from the under surface of the placenta to join the neighbouring organs and tissues. The largest vascular connexion to the underlying tissues was a large vein which opened directly into the common iliac vein of that side, and which was necessarily torn across in peeling off the placenta. The placental tissue was healthy throughout, but at the spot where the mass had bulged into the abdominal wound a slough the size of a crown piece was being gradually thrown off. No pus was found anywhere, but low down in the right of the true pelvis, below the placental attachment, there existed a pocket of red grumous fluid amounting to about an ounce and a half, and formed apparently of blood undergoing retrograde change.

Remarks.—In the light of the post-mortem examination it is easy to trace the course and development of this case. Clearly an impregnated ovum became arrested in the ampulla of the right tube, or at all events in the outer part of this tube. As growth proceeded, the Fallopian tube became distended, and probably the membranes of the increasing ovum bulged out from the tube into the peritoneal cavity in the manner described by Mr. Bland Sutton and others. At the time when Mr. Archer Wood was called to see the patient a partial separation of some of the chorionic villi had taken place and internal hæmorrhage had resulted—or, in other words, a tubal miscarriage was threatened. The blood loss and separation were not, however, sufficient to kill the child or to destroy the vitality of the ovum, and so growth proceeded. The pain, marked anæmia, and prostration leave very little doubt as to the occurrence of the internal bleeding, and the recurrence in a slighter form of the accident at one week's and again at two weeks' interval renders the probability even greater. The further growth of the ovum dragging up and elongating the involved Fallopian tube and leading to the implication of other neighbouring organs and tissues is just what one might expect. It is interesting to note that, though a marked decidual membrane had been formed inside the uterus, this was retained throughout the pregnancy and was not thrown off in the early months in the usual way. There was little in the necropsy to explain the cause of death. No general peritonitis existed, no intestinal obstruction, and no collection of pus, and yet the clinical history and temperature chart suggest most strongly that the patient died from some form of blood poisoning. Bearing in mind the existence of a superficial slough on the part of the placenta which bulged into the abdominal wound and was most exposed to the action of microbes, it would seem probable that this was the source and supply of the septic material which poisoned and overpowered the feeble resisting powers of the woman. In all cases of extra-uterine fœtation advanced to nearly full term the most important and the most difficult question is the method of dealing with the placenta. The necropsy in this case showed most clearly that any attempt (either primary or secondary) to remove the afterbirth would have led to rupture of the large iliac vein and most certainly to a fatal hæmorrhage. The method which was adopted in the present instance must always expose the patient to the risk of septic poisoning, and I shall not again willingly resort to it. Should another similar case come under my care I shall tie and divide the cord close to the placenta, remove as much of the membranes as may be possible, and then close the abdominal incision entirely, leaving the placenta untouched. There would seem to be no reason why the latter organ, which has rested in the abdomen for some months in vital connexion with surrounding parts, should not continue its existence, gradually undergo retrograde change, and form a quiescent tumour of lowly organised fibroid tissue. It was interesting to note at the operation that the placenta was unusually large and developed; also to observe at the necropsy that the organ was full of dark fluid blood and that no considerable degree of blood-clotting had occurred in the large vascular spaces.

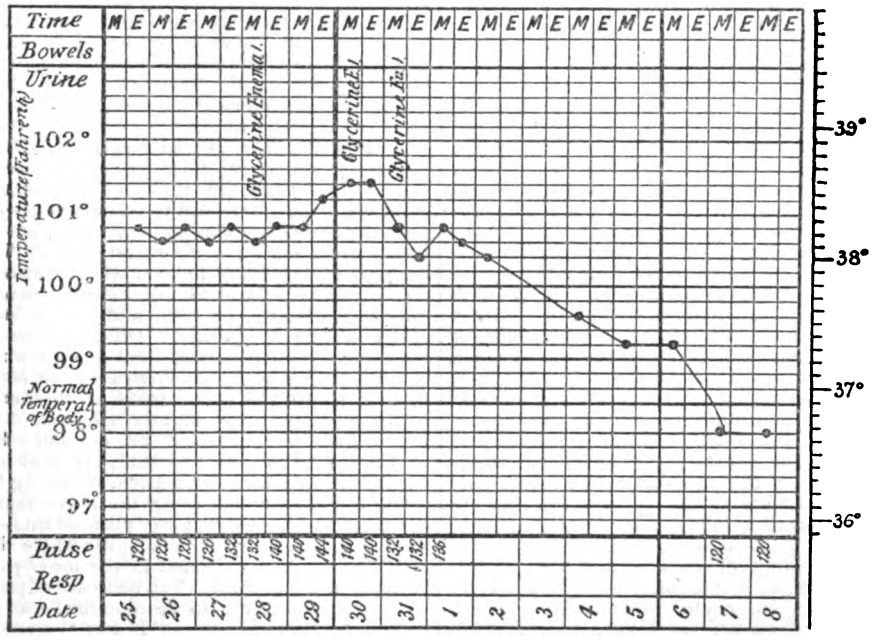
THREE SUCCESSFUL SPLENECTOMIES.

BY J. BLAND SUTTON, F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE MIDDLESEX HOSPITAL.

WITHIN the space of six weeks I have performed splenectomy three times, happily in each instance with a successful issue. As the cases present features of clinical interest I venture to record them.



CASE 1. *Enlarged spleen; recurrent jaundice.*—A girl aged seventeen years was placed under my care by Mr. Arthur Wyborn. She was thin and very deeply jaundiced; a large, firm tumour occupied the left half of the abdomen and extended from the costal arch to the pelvis. This tumour exhibited no notches and was dumb to auscultation. There was amenorrhœa of three months' standing, but the pelvic organs were normal. The patient stated that since the age of five years a tumour had been known to exist in her "left side" and had never troubled her until the last two years, when she began to experience dragging sensations, accompanied by jaundice. The attacks of jaundice had now become so frequent and she felt so ill that she was incapable of following her vocation. On her admission to the Chelsea Hospital for Women she was put to bed. In a few days the jaundice began to fade and the spleen markedly decreased in size. Dr. Comyns Berkeley estimated the red corpuscles to be 4,500,000 per cubic millimetre, and the leucocytes were in the proportion of 1 to 122 of the red. Leucocythæmia was excluded, and I came to the conclusion that this enlarged spleen became engorged with blood when the patient was up and about, and its drag on the stomach caused kinking of the duodenum and common bile-duct, leading to recurrent jaundice and vomiting. In August, 1895, with the full consent of my colleagues, I exposed the spleen through an incision in the left linea semilunaris. The viscus extended from the diaphragm to the true pelvis, its extremity being in contact with the uterus. Dr. Giles gently supported the spleen whilst I secured the slender parts of the gastro-splenic omentum with plaited silk. By the time I was ready to secure the main vessels the viscus had greatly diminished in bulk. There was some anxiety in securing the suspensory ligament, for the dragging necessary to bring it within the sphere of operation produced great interference with respiration. With caution this was successfully overcome and the spleen cut away. I took the opportunity to examine the gall-bladder and found it larger and thicker than usual; the stomach was large and reached below the level of the umbilicus. The wound was secured in triple layers, and the patient returned to bed. She rapidly recovered from shock, quickly convalesced, and left the hospital with rosy cheeks sixteen days after the operation, feeling, as she expressed it, "remarkably well." The spleen, deprived of blood, weighed two and a half pounds, and on microscopical examination was found to be fairly normal in structure.

CASE 2. *Enlarged spleen; anæmia.*—Whilst the patient whose case has just been detailed was under observation, Mr. Trist and Mr. D. Thurston placed under my care a girl five years of age with an abdominal swelling which they regarded, and rightly, to be an enlarged spleen. The viscus was so large as to extend across the ilio-costal space and dip into the iliac fossa. On palpating its border the characteristic notches could be felt with great distinctness. Mr. Trist had watched the girl with great interest for many months and had found drugs so useless in this instance that he deemed it necessary to seek the aid of a surgeon. The girl was admitted into Middlesex Hospital and carefully watched. Leucocythæmia, rickets, syphilis, and lardaceous disease were excluded. Coming, as this patient did, "on the heels," as it were, of Case 1, I could scarcely fail to realise

Digitized by Google

that I had really to deal with an early stage of the splenic enlargement which was found in that case. After very deliberate consideration and full explanations to the parents, with the assistance of Mr. Leopold Hudson, I deprived this patient of a spleen weighing ten ounces. She recovered in an extraordinary fashion and, thirteen days after the operation, was promenading the ward and appeared to be the most cheerful inmate of the institution. She is, as far as records show, the youngest child on whom splenectomy has been carried out.

CASE 3. *Wandering spleen.*—A thin, spare woman thirty-two years of age, the mother of five children, was placed under the care of Dr. Heywood Smith on account of a mobile tumour in the abdomen. The patient had been aware for ten years that she had a hard, movable body in her abdomen, but it had become larger and more troublesome during the last two years. Dr. Heywood Smith soon satisfied himself that the suspected tumour was a spleen, and kindly asked me to see the patient. At the consultation I found a fairly firm body, in shape like a parabolic mirror, with its convex surface in contact with the anterior wall of the abdomen, floating on the intestines. It could be pushed into the left hypochondrium or depressed into the hypogastrium; with a little manipulation it could be conveyed into the iliac, lumbar, or umbilical regions. It was clearly a wandering spleen, and is certainly the most prodigal abdominal viscus which has come under my notice. In September, with Dr. Heywood Smith's assistance, I removed this erring organ in the following manner:—When the patient was placed on the operating-table no tumour could be felt with certainty, but I perceived some resisting body when deep pressure was made in the hypogastric region. An incision was made in the left linea semilunaris, and on dipping my hand into the pelvis I recognised the spleen in the hollow of the sacrum and drew it forth. The pedicle, rounded, very thick, and hard, was transfixed and secured with four plaited silk ligatures. The detachment of the spleen was followed by an abundant flow of blood, and two forcible but narrow jets of arterial blood issued from the cut surface of the pedicle. The stump was retransfixed with three silk ligatures on the distal (spleen) side of the first row of sutures, and, as the open, everted mouths of two large arteries were visible on the face of the pedicle, for the security of the patient I ligatured them separately with silk. The pulsations of a large artery in the thick part of the pedicle were unpleasantly obvious as it was allowed to retreat into the abdomen. The wound was secured in triple layers and the patient returned to bed. During the four hours subsequent to the operation there were marked signs of shock, but no pain; convalescence was astonishingly rapid. The spleen weighed eighteen ounces; a splenculus occupied the hilus. Histologically it appeared normal.

The future course of these patients will be watched with great care, but I do not apprehend any evil results. More than three years ago I removed a wandering spleen from a woman twenty-two years of age; she is at the present time in good health, notwithstanding an attack of pleurisy six months ago. I have performed splenectomy four times, and in each case with a satisfactory result. In the early part of this year two other patients were placed under my care for the purpose of splenectomy, but I did not consider them suitable cases for so formidable an operation, for I am convinced that in order to meet with success in splenectomy it is necessary to very carefully select the cases.

Queen Anne-street, W.

HE PATHOLOGICAL CHANGES OF THE LABYRINTH.[1]

BY PROFESSOR POLITZER
(OF VIENNA).

IN seeking an explanation of the various troubles and defects of hearing it is requisite to trace out their causes or, in other words, to ascertain the pathological lesions that occasion them. This paper will, therefore, be devoted to: (1) a review of all the investigations upon these lesions in the labyrinth that have been made by many eminent observers; and (2) a statement of personal observations from my own studies in the field of pathological anatomy extending over many years.

Our knowledge of the pathological changes of the labyrinth barely extends beyond the second half of this century. The reason for this scientific hiatus depends mainly upon the imperfection of methods of microscopic examination, which were only successfully remedied about the period indicated, as witnessed by the discovery then made by the illustrious Italian Professor Corti of the histological structure of the cochlea, and the very striking and well-known researches subsequently undertaken by Böttcher, Moos, Steinbrügge, Habermann, and others. Nevertheless, many difficulties still exist, such as the impossibility of making post-mortem examinations at once, the meagreness of proofs of labyrinthine affections during life—conditions which hitherto have not enabled us to go beyond the gross anatomical facts of

[1] An address delivered at the Fifth International Congress of Otology, held at Florence from Sept. 23rd to 28th, 1895.

Digitized by Google

labyrinthine pathology. The knowledge so acquired will not have its full value until we have succeeded in connecting it with the clinical phenomena produced by these anatomo-pathological states. Unfortunately, as yet there are only a few isolated instances in which anatomical facts have been connected with clinical observations made during life. The various pathological changes in the labyrinth comprise (1) hyperæmia; (2) hæmorrhagic extravasations into the labyrinth; and lastly (3) inflammations of the labyrinth, primary as well as secondary.

1. *Hyperæmia.*—Easy of recognition anatomically, hyperæmia is of special importance clinically, since it may give rise to subjective noises in the ears, vertigo, and disturbances of hearing. The highly interesting and exhaustive researches made by Dr. Eichler in Professor Ludwig's laboratory at Leipzig upon the vascular system of the labyrinth established the fact that the labyrinth is provided with a special system of vessels, of which the arterioles arise from the internal auditory artery and penetrate through many ramifications into the different parts of the labyrinth, where they break up into capillaries in the cochlea, the vestibule, and semicircular canals, and thence pass into venous capillaries which find an outlet into the venous system of the brain. This special labyrinthine vascular system has numerous anastomotic connexions with neighbouring parts, notably with the tympanic cavity. I was the first to ascertain, by means of microscopic sections treated with osmic acid, that the vessels of the mucosa of the tympanum pierce the bony part of the promontory and anastomose with the vessels of the lining membrane of the labyrinth—an anatomical fact confirmed in the course of pathological investigations. The secondary hyperæmia here meant is particularly that produced by various infective states, notably typhus fever and diphtheritic scarlet fever. But another common cause of hyperæmia is to be found in certain obstacles to the reflux of the venous blood of the labyrinth towards the cranial cavity, such as cerebral tumours and the pressure they exert on the cerebral veins, particularly tumours of the base of the skull growing into the internal auditory meatus and thus compressing both the internal artery and vein. States of labyrinthine hyperæmia are also due to the influence of sympathetic nerve action; the symptoms by which they are indicated—a rapid colouration followed by an equally rapid pallor of face, of external meatus, and of tympanum, tinnitus, and vertigo—admit of no doubt in this regard. There are some forms of hyperæmia which are merely transitory, supervening on acute inflammation of the tympanum or dependent on nervous influence, and which are not then followed by functional derangements. But permanent hyperæmia, caused by chronic inflammation of the tympanum or by arrest of circulation, gives rise to various disorders and persistent troubles. The changes resulting therefrom are enlargement of vessels, pigmentary exudation, and thickening of the membranous parts of the labyrinth and of its lining. This subject will again be referred to.

2. *Hæmorrhagic extravasations.*—Hyperæmia often eventuates in extravasations into the labyrinth, but the latter may be also produced apart from pre-existing congestion. They often occur in infectious diseases, as typhus fever, scarlet fever, diphtheria, small-pox, tuberculosis, chronic nephritis, diabetes, leukæmia, &c., as well as in disorders of circulation due to organic lesions of heart or lungs. In the last-named cases the hæmorrhages must be ascribed to defective circulation, whilst in infectious diseases they are due to changes induced by the action of the specific microbes, which cause diminution of the resistance of the vessel walls. In every case these extravasations take the form of circumscribed hæmorrhages or more extensive effusions of blood in different parts of the labyrinthine cavity. As Knapp and myself have ascertained from post-mortem examinations, these hæmorrhages are met with more commonly than is generally believed in chronic suppurations of the tympanum, especially in those which are complicated with caries, and their frequent presence demonstrates how numerous must be the anastomoses between the vessels of the tympanum and those of the labyrinth. The most interesting forms found by Moos, Steinbrügge, and myself in cases of hæmorrhagic perimeningitis, and of hæmatoma of the dura mater, and also in tuberculous meningitis, are found in part along the course of vessels or nerves and in part between the lamellæ of the bony spiral lamina and in the spiral ganglion, besides hæmorrhagic effusions in the trunk of the acoustic nerve and the formation of thrombi in the external auditory artery. The labyrinthine hæmorrhages which go by the name of "Ménière's disease" are confined to a single case examined post mortem by this observer: it was the case of a young girl who suffered during life with attacks of vertigo, nausea, and disturbance of coördination; but as no other parallel case has been since observed the anatomical basis of Ménière's disease is still lacking, and we ought not, therefore, to speak of a Ménière's "disease," but only of Ménière's "group of cerebral symptoms," which he was, however, the first to correlate with labyrinthine affections from the clinical point of view. It has not been demonstrated as yet that the labyrinthine symptoms frequently observed after the use of certain drugs, such as quinine and salicylic acid, &c., can be produced by hæmorrhages in the labyrinth; in this matter we have only presumptive evidence based on experiments on rabbits made by Fentner. Just as is the case with hyperæmia of long duration, so also do blood extravasations frequently produce pigmentary exudations in the labyrinth: hæmoglobin is then deposited on the membranous parts quite as much as on the walls of the labyrinth, in the form of irregular brown or blackish patches firmly adherent to the tissues of the organ. These pigmentary deposits no doubt irritate the extremities of the auditory nerve and consequently produce subjective tinnitus.

3. *Inflammations of the labyrinth.*—These are either primary or secondary; their pathological relations are more fully known than are those of the changes previously described. Yet in regard to primary forms of inflammation we know little except as to their issues, but not the changes which occur during their early stages. The pathological changes of secondary inflammations, concerning which we possess more precise ideas, result either from acute or chronic infectious diseases, or from a similar inflammation in the cavity of the tympanum. Other writers besides myself have been able to determine that the most marked of these changes are *especially manifested in the lower parts of the cochlea*, whilst the upper parts of this organ are found to be comparatively slightly affected. We are driven to hypothetical reasons to account for this state of things. The most probable is that of Steinbrügge, who thinks that an inflammation, spreading from the cranial cavity to the labyrinth along the nerve ramifications to the cochlea, first reaches the lower plane of this structure, just as in cases of cerebro-spinal meningitis where these lesions are at the very first manifested in the lower parts of the scala tympani of the cochlea. The first case of primary inflammation of the labyrinth to be described was brought by me before the Milan Congress. It was the case of a lad aged thirteen who had been deaf and dumb from the age of two and a half years owing to a labyrinthine otitis, and one could see in the preparation by aid of a lens the complete invasion of the labyrinth by osseous tissue, and the ossified cochlea, the outlines of which are clearly distinguished from the bone that surrounds it. The anatomical changes produced from infectious diseases arise from the invasion of the labyrinth by specific microbes or by purulent material. From these invasions there results an inflammation of the investment and membranous parts of the labyrinth, which leads either to destruction of tissue or to a proliferation of connective tissue that may fill the cavities of the organ entirely or partially and terminate in ossification. These changes are apparently more or less intense according to the more or less advanced degree of inflammation; slight thickenings (*gonflements*) of the labyrinthine lining, or else numerous filaments extend between the bony walls and membranous parts up to the point of completely filling all the cavities with osseous tissue. We owe to Moos the description of the anatomical changes that supervene on infectious diseases, such as scarlet fever, diphtheria, and measles, by the invasion of specific micro-organisms that takes place into the labyrinth through the lymphatic channels passing from the tympanum to this organ. The action of these micro-organisms results in the formation of connective tissues which subsequently ossify, besides necrosis with degeneration of such tissues, caused either by thrombosis of capillary vessels or by the direct action of the virus on the tissues themselves. The character of the grave changes thus produced is in general, except for a few modifications, the same as is found after *diphtheria*, which was the first to be specially studied by Moos. Although he did not happen to determine the presence of the specific microbe of diphtheria, he established in every case the fact of a secondary infection by streptococci, which he detected in nearly all the tissues—in the

Digitized by Google

endo- and peri-lymphatic spaces just as freely as in the vestibular aqueduct, in the ramifications of the acoustic nerve, and in the bony cavities of the petrosa itself. The destructive changes occasioned by this invasion are the same as those just mentioned, and we cannot wonder at their extent knowing how destructive are the effects of the presence of streptococci *en masse*. The results of the infective labyrinthine affections developed during or after *measles* are very similar; they are also described by Moos, who attributes the destructive changes in the labyrinth ensuing on this disease to the same cause—viz., streptococcic invasion of the organ. The disintegrating action of this microbe is shown in fatty degeneration of the endothelia of the bloodvessels, leading to coagulation, thrombosis, and vascular engorgement, followed by colloid changes of the labyrinthine tissues, and other destructive lesions in the periosteum, the osseous parts of the cochlea, and the ramifications of the auditory nerve.

The changes following upon *cerebro-spinal meningitis* were studied by Heller, who was the first to prove that the deafness resulting from this affection was due to suppurative inflammation of the labyrinth. The aqueduct of this organ is the route for this invasion, which particularly involves the cochlea, this being in direct communication with the cerebro-spinal space, where the exudation is seated. These changes mainly consist in destruction and atrophy of the membranous parts of the labyrinth and of the ramifications of the auditory nerve, in partial or complete distortion of the organ of Corti, in atrophy of the cells of the spiral ganglion, and in the deposit of amorphous detritus mingled with a few cells; lastly, forming the remnant of the original inflammation, there is a new formation of connective tissue, which may undergo partial calcification. I myself have ascertained the frequency with which secondary affections ensue on chronic suppuration in the middle ear, which may occur either after the destruction of the labyrinthine fenestra by the spread of inflammation to the membranous parts of the labyrinth, or actually without any apparent lesion of the labyrinthine wall by the extension of the morbid process through bloodvessels and lymphatics by means of the anastomosis which exists between those of the tympanic cavity and of the labyrinth. As regards the first variety of these affections I may recall a case which I described at the Brussels Congress, in which the base of the stapes had been destroyed by granulations of connective tissue following suppuration, their growth extending nearly into the vestibule of the labyrinth, as shown in the preparation I exhibited. Subsequently I showed the second variety of these secondary inflammations in another preparation obtained from a deaf woman ninety-three years of age, in whom the external auditory meatus was filled with cholesteatomatous masses formed after suppuration. In the first preparation the outer wall of the vestibule of the labyrinth was found to be coated with tuberculous epithelioid granulations, which were also distributed over the lateral wall and the base of the utricle. In both cases marked labyrinthine symptoms were entirely absent. I have, moreover, discovered in a certain number of cases of chronic suppuration the residues of chronic inflammation in the cochlea in the form of proliferation of connective tissue with simultaneous partial ossification of this tissue, a change which is more frequently seated in the scala tympani. Another variety of exudation into the labyrinth (hitherto little known and first pointed out by me) is that which is brought about by the presence of some obstruction in the internal auditory meatus, causing compression of its bloodvessels, and thus producing exudation as the result of blood-stasis. I may cite as a conclusive instance on this point an observation I made in a woman aged sixty-three years, who was attacked with deafness of the left ear in the course of a cancerous affection of the side of the neck, where the disease had penetrated into the cranial cavity through the base of the skull. The malignant growth had advanced towards the left petrous bone, surrounding and compressing the carotid artery and jugular vein, and then sprouting into the interior of the internal auditory meatus. The exudation, which consisted of a mass of granular material, was in part situated on the cochlear lining and in part on the lamina spiralis. There was no appreciable change in the tympanic cavity and Eustachian tube.

The labyrinth may also be affected in cases of *leukæmia*, and pathological changes may then ensue in this organ which lead to total deafness. The first demonstration of this fact was made by me at the Brussels Congress in the case of a young man thirty-two years old who had long since been attacked with suppurative otitis media, and who had become deaf one year before his death. The preparations obtained from this case showed: (1) new formation of connective and osseous tissue in the scala tympani of the cochlea; (2) complete invasion of the semicircular canals by connective tissue; and (3) accumulation of lymphoid cells in these canals, in the vestibule, and the scala vestibuli of the cochlea. A similar case has been recorded by Gradenigo, who found extravasations of blood in the mucosa of the tympanic cavity, which had been previously attacked with suppurative inflammation, but no like change in the labyrinth; and then another also by Steinbrügge, who detected changes closely parallel to those which I had pointed out in the case of a young man twenty-three years of age who died from splenic and myelogenic leukæmia, and had been previously attacked with syphilis—namely, adhesions in the tympanic cavity, thickening of the membrane of the fenestra rotunda, invasion of the cochlea by blood extravasations, and nearly total ossification of the semicircular canals.

Affections of the same nature are also produced in the labyrinth as the result of *syphilis*. In this regard the best-known examples hitherto recorded are cases of hyperostosis of the temporal bone with contraction of the labyrinthine cavities and of the internal auditory meatus produced by chronic syphilis, and also, as I have already pointed out, an overgrowth of the labyrinthine capsule with stenosis of the fenestra ovalis, ending in ankylosis of the stapes; and, further, a case of acute suppurative inflammation observed by Schwarze in a syphilitic woman who died from acute purulent meningitis. Among rare anatomical changes ensuing on syphilis I have also noted atrophy and destruction of ganglionic cells in the spiral ganglion and similar lesions of the auditory nerve fibres in the cochlea. The former I observed and described in the case of a man fifty years of age, who had been deaf and syphilitic for ten years; whilst the latter were ascertained by Moos and Steinbrügge. Further, I am reminded by an interesting observation made by Kirchner concerning the pathological changes of the bloodvessels of the labyrinth after syphilis in a patient the subject of tertiary syphilis, consisting in a small-celled infiltration of the coats of the vessels identical with that described by Heubner in the cerebral vessels of syphilitic subjects. The concomitants of these changes appear in the shape of fatty degeneration and pigmentation of endothelial cells, proliferation of connective tissue, and obliteration of the vessels here and there. These changes as a whole present similar characters to those proceeding from chronic inflammation above mentioned. Thus in two cases of syphilis Moos found thickening of the periosteum of the vestibule, hypertrophy of the connective tissue attaching the membranous to the bony parts of the labyrinth, and in one of the cases he ascertained the presence of calcareous concretions in the lining of the vestibule. Gradenigo has shown that this connective tissue may in the later stages become ossified, a change which he thought was attributable to hereditary syphilis in a young tuberculous girl aged fifteen years.

Another class of labyrinthine affections is that arising from *tuberculosis*, although primary tuberculous disease has not yet been found. Such observations as have been made on these rare conditions are confined to subjects in whom the middle ear was invaded by tuberculosis, which had encroached upon the labyrinthine cavity and capsule. The features of this affection are denoted by the inflammation, as soon as the capsule has been perforated by ulceration, extending over the lining of the cavity and the membranous parts of the labyrinth, thereby producing, on the one hand, necrosis of tissues, and, on the other, a proliferation of newly formed connective tissue which partially fills the labyrinthine cavities.

In the list of these pathological changes of the labyrinth must also be reckoned *primary affections of the labyrinthine capsule*, to which I drew attention at the Rome Congress. I then demonstrated that in a large number of cases regarded as dry chronic catarrh of the middle ear osseous growths of new formation are met with in the capsule around the fenestra ovalis, these proliferations extending in the direction of the fenestra and leading to ankylosis of the stapes or complete occlusion of the fenestra. In an advanced stage of the disease the bony overgrowth comes to penetrate into the cavity of the labyrinth, notably into the scala tympani, subsequently leading to complete disorganisation of the membranous parts of the labyrinth and organ of Corti.

Finally, I have placed among similar affections which

Digitized by Google

I have pointed out and described the *depression of Reissner's membrane*, resulting from increased extra-labyrinthine tension on the organ of Corti, as first referred to by Steinbrügge and later by myself and other writers, and I cited the case mentioned by Steinbrügge of a boy aged twelve years who died from a cerebral tumour, in which the increase of intra-cranial pressure was shown during life by the presence of optic neuritis, and another case described by Gomperz of a tuberculous subject who died from internal pachymeningitis and cerebral œdema, observing that in both cases the membrane of Reissner was found depressed to such an extent that only a mere slit existed between it and the membrane of Corti.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF PROLONGED LABOUR.

BY R. D. RUDOLF, M.B., C.M. EDIN.,
LATE RESIDENT PHYSICIAN TO THE ROYAL INFIRMARY AND ROYAL HOSPITAL FOR SICK CHILDREN, EDINBURGH.

ON April 4th, 1893, I was called to see, in consultation with a native medical man, a case of prolonged labour, which had only come under his notice that morning. The patient was a middle-aged Hindoo woman and a multipara. She had gone to full term. The history obtained from her relatives was that she had been in a state of labour for eight days, and that as the native midwives could not effect delivery they had brought her into the town of Sewan, a distance of thirteen miles. According to the apparently usual custom among the natives, she had been allowed neither food nor drink since labour began. The patient was found to be a well-nourished woman (although, according to her friends, she was much reduced) and rather above the average size. She lay on her back in a semi-conscious state, muttering occasionally to herself. The skin was cold and clammy, respiration hurried and shallow, and the pulse at the wrist scarcely to be felt and not countable. Auscultation over the heart showed that this organ was beating from 150 to 170 per minute. The tongue was dry and glazed. An intensely fetid discharge issued from the vagina. On examination per vaginam a face presentation with the chin towards the right sacro-iliac synchondrosis (first position) was made out low down in the vagina. The child had evidently been dead for some days. There was complete absence of pains, and the uterus appeared to be completely relaxed. On passing a catheter an enormous quantity of rather high-coloured clear urine came away. The native medical man had already attempted to apply a pair of short forceps without success. After some brandy had been given to the patient I adjusted a pair of Simpson's axis-traction forceps, and by easy stages, and without any great force being used, delivered the head, complete rotation forwards of the chin taking place. The patient became very collapsed, so a hypodermic injection of ether was given and the body was delivered without difficulty. The child was a large male and was very much decomposed, the face in particular being almost denuded of soft tissues. A drachm of extractum ergotæ liquidum was given by the mouth. In half an hour, no pains having appeared, I removed the placenta by introducing the hand into the uterine cavity. No hæmorrhage occurred, but a great deal of intensely fetid, reddish fluid came away. The uterus was then very thoroughly washed out with a corrosive sublimate solution (1 in 2000), and the external parts were cleansed with a strong solution of phenyle. Some milk and brandy were given and hot bottles placed around the patient. That evening (six hours later) the temperature was 97° F. and the collapse was still great, but the pulse was a shade stronger. Milk and brandy were given every half hour. Next morning the temperature had become normal and the pulse counted at the wrist was 115 to 120. The patient was much stronger and could talk sensibly. A douche of corrosive sublimate solution (1 in 3000) was used and the urine was drawn off with a catheter. That evening the temperature had risen to 100°, and five grains of quinine were given. Thence onwards the vagina was washed out twice daily with corrosive sublimate solution (1 in 3000) and the phenyle solution alternately. Fluid nourishment was continued at short intervals. On the second day the uterus was felt for the first time definitely contracted; on the third day the patient micturated and the bowels were moved naturally; and from that time forward she made an uninterrupted recovery and was sent home at her own request a week later. Several weeks afterwards she reported herself as quite recovered.

This case was undoubtedly one of uterine inertia in a previously healthy woman, and this state was brought on by the non-rotation forwards of the chin along with a distended bladder. It seems worthy of note on account of the complete recovery of the patient after such a prolonged labour, such extreme sepsis, and such great prostration. Also it is perhaps an interesting record of a far advanced stage of inertion such as would seldom or never be seen in a country such as England, where proper medical attendance would be sure to be availed of long before this state was reached.

Sewan, Sarun, Bengal.

THREE CASES OF CANCER OF THE GASTRO-INTESTINAL TRACT DEVELOPING DURING PREGNANCY.

BY JAMES OLIVER, M.D., F.R.S. EDIN.,
PHYSICIAN TO THE HOSPITAL FOR WOMEN, SOHO-SQUARE, LONDON.

WHEN the stomach becomes infected by cancer during pregnancy the resulting sickness is apt to be attributed to the molecular variations going on in the uterus. If, however, a patient who has borne two or more children and who has never experienced sickness during pregnancy complains of this symptom, and it is evident that the cause is neither uterine nor renal, then we should suspect organic disease of the stomach. In the ordinary course of events sickness, as I have elsewhere[1] remarked, is seldom observed during pregnancy when the tone of the uterus is more or less impaired.

CASE 1. *Cancer of the pylorus; sickness noted from the sixth week of pregnancy.*—The patient was a woman aged forty, who had been married five years and had had three children. The last child was born on March 2nd. At the time when the patient considered herself to have been pregnant for six weeks she began to complain of sickness, a symptom which she had complained of during the early months of her first pregnancy, but which was absent during her second. As the sickness persisted after the third confinement the patient presented herself at the hospital, and on examination I detected a small cake-like, movable, and slightly tender mass close to the umbilicus. Death occurred after the disease had probably been in existence about two years.

CASE 2. *Primary cancer of the stomach and secondary of the pelvic peritoneum; sickness noted from the seventh month of pregnancy.*—This patient, aged thirty, who had been married eight years and had had four children, was seen by me in consultation with Dr. H. P. Miller of Stoke Newington-road. Her last child was born on Aug. 26th. About the seventh month of pregnancy she began to complain of sickness, a symptom which she had never complained of during her former pregnancies. As the sickness persisted after parturition, and pain was experienced in the lower abdomen, Dr. Miller desired me to see the patient. The abdomen was slightly prominent in consequence of the inflation of the bowel, and with difficulty a small, hard, and nodular swelling was detected to the right of and above the umbilicus. Behind the uterus was felt a hard mass with a keel-like ridge, which pushed down the vaginal roof. The pelvic mass was not tender. Death occurred five months after the fourth confinement.

CASE 3. *Cancer of the sigmoid flexure developing during pregnancy.*—The patient was a woman aged twenty, who had been married eighteen months, and had had one child. The child was born two months before the patient came under my observation. Ever since the confinement a small swelling had been observed in the left half of the abdomen. The following were the physical signs. In the left iliac region, about one inch to the inner side of the superior spine of the ilium and extending from its level upwards for three

[1] Diseases Peculiar to Women, p. 24.

Digitized by Google

inches, was a small, annular, hard, and fixed swelling, which was tender to the touch. The cervix uteri was central and the body of the uterus was felt in front lying on the pelvic floor. There was no deposit in the pelvis. Death occurred five months after parturition.

Gordon-square, W.C.

A CASE OF EMPYEMA OF THE ANTRUM OF HIGHMORE OF SEVEN YEARS' DURATION.

By GEORGE PINDER, M.D., B.C. CANTAB.,
LATE ASSISTANT HOUSE PHYSICIAN, GENERAL HOSPITAL, NOTTINGHAM.

A MAN aged thirty-four years sought advice for constant pain referred to the left temporal, mastoid, and occipital regions; he complained also of more or less constant nausea and of palpitation of the heart. A careful physical examination failed to elicit any positive evidence of organic disease, and inquiry was then directed towards a purulent discharge from the left nostril disregarded by the patient, since he had had it for quite seven years and "had got used to it." He explained that the discharge was due to an attack of influenza seven years previously, and that his club attendant had told him that "there was a piece of dead bone in his nose." On rhinoscopic examination the anterior portions of the septum and of the left inferior turbinal bone were seen to be studded with numerous small sessile vascular polypi, and pus was observed oozing from the situation of the middle meatus. The purulent discharge was constant and offensive; it varied much in amount and was not affected by the position of the head, save that at bedtime it "ran down the back of the throat." The left upper molars were carious but not painful. There was tenderness on pressure over the situation of the left infra-orbital nerve. Under ether the decayed teeth were extracted, and, in view of the long-standing nature of the case, two holes were drilled into the antrum, one in the situation of the second molar and the other through the canine fossa. A pyogenic membrane, forming a very complete cast of the antral cavity, was removed by syringing with an antiseptic solution, together with a quantity of pus and caseous material. The polypi were removed and their bases cauterised. The troublesome symptoms ceased almost immediately, and the patient is now, after some ten weeks' treatment, perfectly well. The only remarkable feature of the case, and its best apology for publication, is the extraordinary length of time the disease had existed unrecognised, the patient having been under almost constant medical care since the first appearance of the nasal discharge. It emphasises once more the importance of thorough intra-nasal examination in all cases of purulent nasal discharge.

THE NEW ASYLUM FOR WEST SUSSEX.—The violent opposition to the county council's scheme for erecting a new lunatic asylum for the administrative district of West Sussex has not been heard of lately, and meanwhile the new building is getting on apace. It stands about a mile from Chichester, and is built from the design of Sir Arthur Blomfield. The executive buildings stand in a block in the centre of a series of six blocks for the reception of the patients; the latter blocks are to be connected by underground corridors. The chapel is to cost £4000 out of £114,669, the amount of the contract. The total expenses will probably be nearer £200,000, but the original estimate was far in excess even of this figure. Water has been found at a depth of 400 ft., and a huge water tower some 100 ft. in height will serve the buildings. The asylum will accommodate 450 patients, and is capable of being extended to receive another 150. Up to the present time the asylum at Hayward's Heath, in East Sussex, has been the only one in the district, but for years patients have had to be drafted thence to Berrywood, Salisbury, and establishments at other places.

MIDDLESEX HOSPITAL.

TWO CASES OF INGUINAL HERNIA PRESENTING UNUSUAL CHARACTERS.

(Under the care of Mr. HENRY MORRIS.)

THE rarity of the first of these cases is shown by the fact that the condition is not described in our text-books or in the special treatises on hernia to which we have been able to refer. Mr. William Anderson has described[1] a similar condition met with by him in three cases where he operated for left inguinal hernia. He speaks of it as "an anatomical variation which has not hitherto been recognised (except as a possibility by Joseph Maclure in his Surgical Anatomy) the absence of a sigmoid meso-colon in the iliac segment of the large intestine." He apparently apprehended some loss of vitality in the portion of bowel which he dissected up and returned, owing to the movement from its attachments, but all three cases recovered satisfactorily. The second case is also an unusual one, for although it is not uncommon to meet with ulceration of the bowel in a case of strangulated hernia, the destruction of tissue occurs at the

FIG. 1.

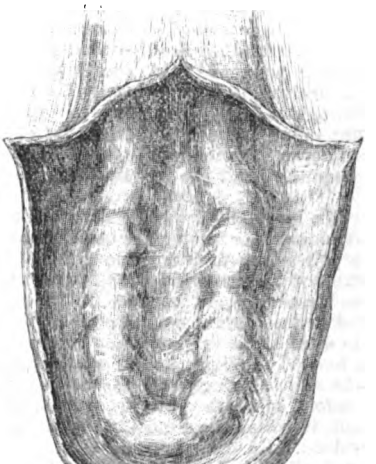

Diagram showing sac open and bowel behind posterior wall of sac—indeed, forming posterior wall of sac.

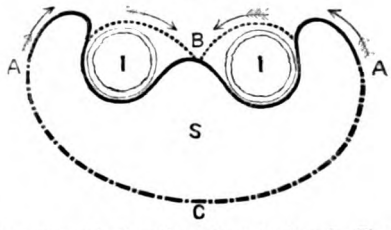
point of strangulation, usually the neck of the sac. Here the ulceration occurred at the fundus of the sac; and the escape of the contents of the intestine was limited by adhesions before the perforation was complete. The resection of the bowel was undertaken under favourable circumstances compared with most cases of operation for ulceration with perforation, the patient being in a condition to permit a prolonged operation and therefore of all necessary care in the suturing. It will be noticed that Mr. Morris resorted to the method of uniting the ends as the most reliable when he had the choice, and did not resort to the use of any of the artificial aids which are recommended by some surgeons. For the notes of the cases we are indebted to Mr. John Murray, surgical registrar.



CASE 1. *Hernia of the sigmoid flexure into the scrotum; part of the sac used to give a complete covering of peritoneum to the bowel, the rest excised; inguinal canal closed*

[1] Medical Press and Circular, 1894, vol. ii., p. 621.

Digitized by Google

by sutures; radical cure.—A man aged twenty-seven years was admitted to the Middlesex Hospital on Feb. 20th, 1893. He stated that he had had a swelling in his left inguinal region for six years, but he was unable to give a definite history as to its first appearance. On examination there was a large inguino-scrotal hernia on the left side, the greater part of which was reducible; the external ring was very patulous. On March 11th, under an anæsthetic, the sac was opened and found to be empty, and behind its posterior wall was a loop of the sigmoid flexure (Fig. 1) with its meso-sigmoid and appendices epiploicæ. The meso-sigmoid blended with the posterior part of the wall of the sac. The sac having been laid open, as shown in Fig. 1, was then dissected, together with the bowel, free of the connective tissue outside it; it was then divided near the bowel, as shown in Fig. 2

FIG. 2.

Shows arrangement of peritoneal sac to bowel. The dotted lines indicate the part of the sac entirely removed. The arrows pass from A, where the sac was cut away, to B, where the cut edge of the remainder of the sac was sutured round the gut.

at A, on each side, and the peritoneum was stitched back, as indicated by the arrows, to the point at B. The bowel thus isolated, and completely enveloped in peritoneum was returned into the abdomen, the rest of the sac was dissected up and ligatured at the neck, and excised: the inguinal canal was closed by three kangaroo-tendon sutures, which also transfixed the ligatured neck of the sac. A counter-opening was made in the lower part of the scrotum, and a drainage-tube was inserted. The superficial wound was sutured and dry dressings were applied. There was some slight suppuration at the lower part of the wound, and an abscess formed, which was opened. After this the wound healed soundly, and the patient was discharged well on May 10th.

Remarks by Mr. MORRIS.—I wish to draw attention, firstly, to the method adopted for freeing the bowel from the sac and utilising part of the sac to form a covering of peritoneum over the surface of the gut which was between the reflected surfaces of the meso-sigmoid; secondly, to the extreme rarity of the sigmoid flexure forming a hernial swelling. I have had to operate upon three or four cases in which the cæcum has formed a hernial swelling, and in which this portion of the gut had the same bearing to the sac as in this case; but I have never before, to my recollection, treated or seen a case like the present, in which the sigmoid flexure was the part of the bowel involved.

CASE 2. *Irreducible inguinal hernia; resection of intestine; castration; recovery.*—The patient, a healthy-looking man aged forty-three years, was admitted to the Middlesex Hospital on May 15th, 1894, with an irreducible inguinal hernia. He stated that he had had a rupture on the left side for twenty years and had been ordered a truss, which he had worn constantly. About five years previous to his admission—namely, in 1889—he noticed a swelling in the right groin, which gradually increased in size and descended into the scrotum. At first he could put it back, but for the last three years it had been irreducible. He had noticed a hard lump in the scrotum for some considerable time, but was unable to state definitely how long it had been present. At the time of his admission there was an inguino-scrotal hernia on the right side; it was partially reducible and resonant over the upper two-thirds, apparently consisting almost entirely of intestine. The skin of the scrotum was red and œdematous, and at the lower part of the hernial swelling, and obviously connected with it, there was a hard, tender, somewhat globular mass about the size of a tennis-ball. It was smooth on the surface and not adherent to the skin. On May 22nd an incision was made over the external abdominal ring; the hernial sac was exposed, the lower part of which was found to be incorporated with the hard mass above described. The sac was opened: it contained a loop of small intestine which was firmly adherent to the bottom of the sac. The adhesions were carefully separated, during which process some purulent fluid and also some fæcal matter from a small perforation in the intestine escaped. The wall of the bowel at the point of attachment was softened and ulcerated, and beyond this, for a distance of two inches on either side, it was ulcerated, infiltrated, and thickened, and had all the naked-eye appearances of an epithelioma of the gut. The loop of intestine was drawn down, and, sponges having been carefully packed all round, clamps were applied above and below the affected area, which was cut away together with a V-shaped piece of the mesentery. The cut edges of each layer of the mesentery were separately sutured with fine carbolised silk, and the ends of the intestine were then united by means of Lembert's sutures. After the bowel had been returned into the abdominal cavity an attempt was made to separate the sac and the mass connected with it from the testicle; this, however, proved to be impossible. Accordingly, the neck of the sac and the cord were separately ligatured and divided, the sac and the testicle being removed together. The wound was closed, a drainage-tube was inserted, and dry dressings were applied. The patient was very faint after the operation, which lasted two hours, but he soon rallied. Nothing was given by the mouth for the first twenty-four hours, after which a teaspoonful of milk every hour was ordered. On May 23rd the temperature was 100·6° F. and the pulse 104; he was very comfortable and free from pain. On the 24th the wound was dressed, and as there seemed to be some tension at the upper part two stitches were removed. The temperature gradually came down and on the 27th was 98·4°. His bowels acted naturally on the 28th, and on June 4th he was ordered solid food for the first time. Some slight suppuration occurred in the upper part of the wound, which delayed his convalescence, but the wound was soundly healed on June 29th, and he was sent to a convalescent home on July 3rd. The excised portion of intestine measured seven inches and was bent on itself so as to form a U the limbs of which were firmly adherent to each other. At the point of attachment, which was situated half an inch above the bend, there was an oval ulcerated area measuring two inches by one inch, in the centre of which there was a perforation opening into the upper part of the bowel large enough to admit a No. 2 catheter. On laying open the intestine the mucous membrane was perfectly healthy except at one spot where the perforation had occurred. The hernial sac was extremely thick, and attached to the lower part there was a hard indurated mass. In the centre of this there was a small cavity containing pus with a distinctly fæcal odour. This cavity communicated with the interior of the sac by a small opening.

ROYAL BERKSHIRE HOSPITAL, READING.

TWO CASES OF PERFORATED GASTRIC ULCER TREATED BY OPERATION; ONE RECOVERY.

(Under the care of Mr. WILLIAM J. MAURICE.)

THESE cases are very good examples of the symptoms produced by the perforation of a gastric ulcer and the method of operation which is required in order to save life when such an occurrence has taken place. There are one or two points in the treatment which these cases serve to emphasise: one is the great importance of early operation, and the other the inadvisability of giving opium, which serves to mask symptoms and produces an apparent improvement which may cause delay in operating. Mr. Maurice gives rather a high estimate of the cases of gastric ulcer which prove fatal by perforation, unless this disease is unusually prevalent in and around Reading. If the number of deaths from this cause was as large in proportion in other parts as it appears to have been there within the past twelvemonth, the profession would consider the question of operation before perforation much more seriously than it does at present. We congratulate Mr. Maurice on his success in the first of these cases.

CASE 1.—A young woman aged nineteen years was seized with sudden acute pain in the left hypochondrium and between the scapulæ at 3 P.M. on Feb. 15th, 1895. She was seen by Mr. A. C. Major, who diagnosed perforation of a gastric ulcer and sent her to the hospital, where she was received at 10.45 P.M. She was a rather anæmic girl, with a history of pain after food for some time past. She lay on her back with an anxious expression; her breathing was rather rapid

Digitized by Google

and shallow; the pulse was 138, inclined to intermit, but of fair volume; and the temperature was 101·6° F. She had vomited, but was not collapsed. The abdominal wall was rigid, and liver dulness was absent. She was seen at midnight by Mr. W. J. Maurice, when her condition was not much changed, though she was stated to be looking distinctly worse. Under chloroform, nine hours after the first onset of symptoms, a three and a half inch incision was made in the middle line above the umbilicus down to the peritoneum, which bulged into the wound; gas escaped at once on the peritoneum being opened. The stomach was drawn out of the abdomen, and a small perforation was readily found on the anterior surface, near the cardiac end, and was secured by two rows of Lembert's sutures. The peritoneum was flushed with water at 110°, a good deal of lymph was removed with sponges, and the wound was closed. The stomach was then partially washed out, and one-sixth of a grain of morphia was injected hypodermically. The patient had a good night. She was fed by nutrient enemata at first, mouth feeding being begun on Feb. 18th, when also the bowels were opened by an enema of olive oil. From this time the progress was satisfactory, although the temperature did not become quite normal for nearly three weeks; there was also some suppuration of a rather superficial character. On March 1st she was suffering from thrombosis of the left saphena vein, which lasted for about ten days. She was put on a fish diet on March 15th and soon got strong and well. She was, however, detained in hospital till April 30th, waiting for admission to a convalescent home.

CASE 2.—A woman aged thirty years was seen in private by Mr. W. J. Maurice at 9 P.M. on March 2nd, 1895. She had been seised shortly before with sudden acute pain in the epigastrium, and more especially between the scapulæ, and had vomited. There was little or no tenderness; the abdominal muscles moved well; the temperature was 98·4° F.; the pulse was weak and rapid; and the liver dulness was normal. She preferred to lie on her left side with the legs fully extended. She was known to have suffered severely from gastric ulcer ten years before, and had been under treatment for dyspepsia recently from time to time. Perforation of a gastric ulcer was at once suspected. She was given one grain of opium pill and was seen again at 10.30 P.M. By this time, though she was still in pain, her pulse was slower and stronger, she had not vomited, and was quite warm. In the belief that she was really better, and that, after all, perforation had not actually occurred, a small injection of morphia was given, and she was left for the night. Next morning it was found that she had changed for the worse in every way. She had not slept, her pulse was very weak and rapid, and her abdomen was beginning to be distended. Unfortunately, from various circumstances, it was impossible to remove her to the hospital till the afternoon. At 4.30 P.M. (nineteen and a half hours after perforation) she was placed under chloroform; the abdominal muscles then moved well; liver dulness was present, but was somewhat diminished. The physical signs, in fact, were but slight. An incision was made in the middle line above the umbilicus; the peritoneum did not bulge, and no gas at first escaped on opening it. A coil of reddened, lymph-covered intestine was seen to be adherent to the stomach. An attempt was made to draw the stomach out of the wound, but it was found to be bound down by old adhesions; a large, thick-edged aperture was, however, discovered, from which food and gas escaped. It was hard to make out its exact anatomical situation, but it seemed to be on the lesser curvature midway between the cardiac and pyloric orifices; above and behind it there was what was taken to be the pancreas, with the gastro-hepatic omentum intervening; the pylorus was displaced downwards. The perforation was extremely hard to reach owing to the matting together of intestines round it; but it was eventually closed fairly satisfactorily with two rows of fine silk sutures, the second row being placed at right angles to the first. The peritoneum was flushed and sponged, and the wound was closed. The operation lasted one hour and a half. The patient had a very restless night, with much hiccough and coffee-ground vomiting. The whole of the next day she was as bad as she could be; the pulse was very feeble and running, and there was a good deal of abdominal distension. On the morning of March 5th she was better after a fair night; the bowels acted very freely and continued to do so constantly till the following day, when she had distinctly improved; there was less distension, the pulse and breathing were quieter, and she no longer passed motions under her. Feeding by the mouth was begun on March 7th, and all went well, with daily improvement, until 3 A.M. on March 11th, when she had a severe attack of vomiting. The pulse again became feeble and rapid, and in the evening she was drowsy and restless, with dusky appearance, though there was no further vomiting. She was given three grains of calomel and one grain of opium. The next two days were marked by increasing weakness with rapidity of pulse, but there was no pain or vomiting, and she rested and took nourishment fairly well. At 9 A.M. on the 14th, while her bed was being put straight, she was seized with sudden pallor and laboured breathing and died in half an hour, unexpectedly.

Necropsy.—The body was fairly nourished. The operation wound was four inches long in the middle line above the umbilicus; from it a small amount of blood-stained purulent fluid escaped. The abdominal wall around the wound was infiltrated with pus; just beneath the wound there was a collection of thick pus shut off from the general peritoneal cavity by adhesions between the small intestine and the abdominal parietes. The small intestines were darkly coloured, empty, and bound down everywhere by recent adhesions. There were occasional patches of lymph, but there was no pus in the general peritoneal cavity. The stomach was greatly dilated, hour-glass in shape, and full of dark, foul-smelling fluid. The lumen at the centre of constriction would only admit the forefinger with difficulty, but at the upper margin of this, just in front of the attachment of the lesser omentum, there was a large ulcer the size of a shilling, with thick, rounded edges. The stomach was adherent to the pancreas behind. So far as could be ascertained, the sutures had held securely. Some scar tissue was found stretching from the edge of the ulcer towards the pylorus. Near the cardiac end of the stomach there were numerous submucous hæmorrhages. The kidneys, spleen, liver, heart, and lungs were examined and found to be normal.

Remarks by Mr. MAURICE.—Perforation of a gastric ulcer is, here at any rate, a far more common affection than is generally supposed. I myself know of at least ten cases which have occurred in Reading within about twelve months. Of these ten cases seven have been operated upon, with three recoveries. Of my own three cases of operation one lived over a week,[1] a second lived nearly a fortnight, and a third recovered; both the fatal cases at one time promised to do well. A comparison of my cases leads me to attach most importance to the following points: 1. Early operation, which means prompt and accurate diagnosis. A single grain of opium may almost completely mask the symptoms. 2. The age of the patient and the degree of collapse. 3. The previous history; long-standing ulcer means matting of parts and also impaired nutrition. 4. The situation of the ulcer; most perforating ulcers are on the anterior wall, but near the lesser curvature they may be hard to get at. 5. A large perforation is more difficult to close than a small one, but more depends upon the extent of the ulcer and the condition of the surrounding tissues. Excision seems to be unnecessary, and would be quite impossible in a really difficult case. 6. Extensive escape of stomach contents, which means much shock at the time and probably extensive peritonitis afterwards. It is a singular fact that in my successful case, as in that of Mr. Walters and some others, recovery was delayed by thrombosis of the left saphena vein.

[1] Vide THE LANCET, June 2nd, 1894.

A FRENCH CONVALESCENT HOME AT BRIGHTON.—A convalescent home at Brighton in connexion with the French Hospital in London is in course of construction at the far end of the parade in Kemp Town. It is expected to be ready for occupation in about a year, and will contain about thirty beds for patients recovering from illness, as well as a certain amount of accommodation for infirm and aged persons. Baron de Courcel, the French Ambassador, laid the foundation-stone on Oct. 5th in presence of a distinguished company of French ladies and gentlemen. Sir William Mac Cormac, consulting surgeon to the French Hospital, also attended, and Dr. Achille Vintras, senior physician to the hospital, in returning thanks to the Ambassador after the ceremony, remarked on the benefits derived by convalescents from residence at the seaside.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

General Meeting.—President's Address.—Radical Cure of Hydrocele.

A GENERAL meeting of this society was held on Oct. 14th, the out-going President, Sir WILLIAM DALBY, being in the chair.

The report of the council was read; it showed the society to be in a flourishing condition. The vacancy in the office of treasurer caused by the decease of Mr. Durham was filled by the election of Mr. Goodsall. Votes of thanks to the President and to the retiring officers concluded the business of the general meeting.

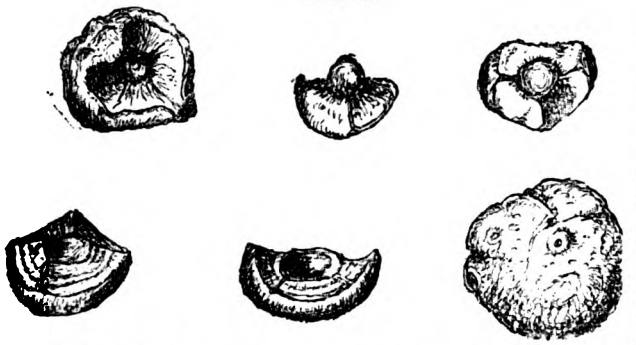
Sir JAMES CRICHTON BROWNE, the incoming President, on taking the chair, thanked the Fellows for the honour they had done him in electing him to fill the office of President. He then delivered his inaugural address, taking for his subject the Generalisation of Specialism. The subject was handled by the President in his usual able fashion; it was rich in original thought, and an attempt to render its substance in abstract form would not do it justice. The following must therefore be considered as merely an indication of the leading topics dealt with. He alluded to the fact that the Medical Society had during the last few years included among its presidents representatives of several of the great specialities into which the profession in its ever-growing heterogeneity tended to divide. He thought this liberal spirit which characterised the policy of this most conservative of medical societies was one of its most admirable features, for it prevented that insulating of the specialities which was a danger both ethically and scientifically, and the impoverishment of professional thought which the withdrawal from its consideration of novel and minute observations must entail. He pointed out that specialism at the present time was inevitable, and no one could train his senses or muscles to consummate expertness in the use of all the now multitudinous instruments of research and treatment. The great thing was to keep the special departments in touch with the main body of the profession, to see that they were conducted on rational lines, and that the departments of practice detached by it did not become refuges for empirics or imperfectly equipped practitioners. He pleaded with specialists of all types and varieties to avail themselves of the advantages which the society offered. While himself proud of being a specialist, he was prouder still of belonging to a great and magnanimous profession, and, in respect of his speciality, he urged that it was hardly a speciality at all, or only in a very restricted sense. It was, indeed, almost coextensive with medical practice as a whole. He regretted that those who devoted themselves to medical psychology were often compelled to spread themselves far beyond medical practice, and to merge their professional capacity in non-scientific and comparatively menial avocations. He admitted, however, that the attempt to completely separate administration from treatment was not likely to prove successful on a large scale. He looked forward to the organisation of hospitals for the treatment of mental disease on the lines submitted to the London County Council by Mr. Brudenell Carter, where psychology could be studied and systematic investigation, teaching, and demonstration carried on. He insisted on the necessity for a just conception of the relation of body and mind, and he alluded *en passant* to the materialistic constructions placed on this relationship—convictions based on sensory stimulation being accorded more weight than was accorded to other classes of belief. He protested against the view that mind was to be regarded as simply a result of cerebral activity or chemical transformations in the nerve centres. The series of phenomena separating mind from matter stood apart: a neural process and a mental process had nothing in common, and the facts of consciousness were not explained by the facts of brain function; in fact, psychology was not merely a branch of mechanics, and mind could have no causal dependence on matter.

Mr. LOCKWOOD then read a paper on the Operation for the Radical Cure of Hydrocele by Excision of the Sac, which we print in full in this issue.—Mr. SWINFORD EDWARDS said that he had only excised the parietal tunic in relapsed cases. If the Edinburgh tincture of iron were used for injecting hydroceles relapses would not be so frequent, as that tincture was twice the strength of the English preparation. The treatment by injection could hardly be expected to succeed if there happened to be any chronic inflammation of the testis present or if the cyst happened to be multilocular. He related the case of a medical man who had cured himself of a hydrocele by the injection of corrosive sublimate of the strength of a grain to the ounce.—Mr. BRYANT said that he had recourse to the operation only after injection had failed to effect a cure. He was convinced that the failure to cure by injection of iodine was because too weak a solution was used. For the last twenty years he had used a mixture of equal parts of the liquor and the tincture, two or three drachms of which he injected into the sac; most of the cases so treated had proved successful. He thought that only the more severe cases should be treated by the operation which had been proposed. Some years ago he tried the effects of hot water as an injection, and he used it in four successive cases. In two of these the hydrocele was cured rapidly, though the injection caused subacute inflammation and a good deal of effusion, which was afterwards absorbed. These cases remained well when heard of long afterwards. The other two cases suppurated, though the water used had been boiled. In a few cases he used carbolic acid, with favourable results. In three cases he had excised the sac, cutting away a considerable portion of the tunic, swabbing out the cavity with chloride of zinc solution or carbolic acid, and then plugging with iodoform gauze. The cavity rapidly contracted without suppuration, and this was a simpler plan than Mr. Lockwood's, especially for elderly patients.—Mr. WALLIS stated that he had operated on seven cases, one of which had suppurated. His method was to scrape the testicle with a sharp spoon, pare away the parietal layer, and then suture the wound, using no drain.—Mr. BIDWELL said that in two cases treated by injection he had subsequently to excise, and then he found some adhesions. In the first case he used a drain, but this was followed by some orchitis, and so afterwards he completely closed the wound without drainage. After excision the patients left the hospital in about ten days, but in injection cases he had as a rule to detain his patients longer than that. In many cases there seemed to be some re-formation of serous membrane. — Mr. LOCKWOOD, in reply, said that the injection of iodine was distinctly a painful process, and one that he would object to undergo himself; besides, it might excite epididymitis or orchitis. In many of the cases he had related the patients had previously been injected with all kinds of fluids, including the Edinburgh tincture. All his cases save one were well within a week and left the hospital in a fortnight. He held that treatment by excision of the sac was simpler and less troublesome as well as less painful than treatment by injection. He admitted that erasion might be desirable in some cases, but none of the instances he related seemed to require it. He adopted drainage because it did no harm and was a wise precaution.

PATHOLOGICAL SOCIETY OF LONDON.

Spontaneous Disruption of Calculi.—Primary Sarcoma of Vagina of Child.—Multiple Polypi of Stomach and Intestines.—Tertiary Syphilitic Lesions in Lymphatic Glands.—Exhibition of Specimens.

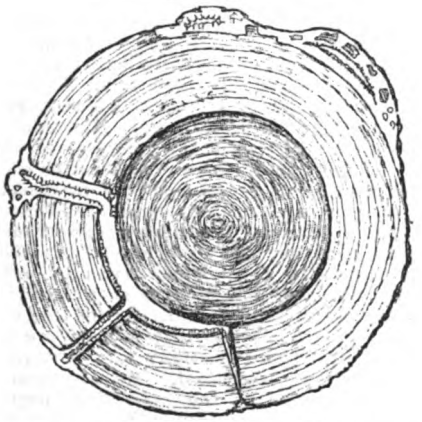
THE first ordinary meeting of this society for the present session was held on Oct. 15th, the President, Mr. H. T. BUTLIN, being in the chair.



On taking the chair for the first time Mr. BUTLIN expressed his thanks to the society for his election. He announced his intention of postponing his address until next year when the society would celebrate its fiftieth anniversary.

Dr. PLOWRIGHT read a paper on the Spontaneous Fracture of Uric Acid Calculi. The subject of the communication was a man aged seventy-two years from whose bladder there were removed 236 fragments and six entire calculi in the process of spontaneous fracture. The base of the bladder was occupied by several sacculi or pockets about half an inch across, which contained the fragments, the calculi, and pus-laden urine. The sacculi were formed by hernia-like protrusions of the mucous membrane between the reticulated muscular fibres of the

Digitized by Google



bladder, and were so placed as never to be emptied during life. The entire calculi were mapped out into segments by elevated ridges, and upon section each segment was seen to be lifted up, being separated from the nucleus of the calculus below and from the other segments by cracks or fissures sufficiently wide to admit the point of a pen-knife. (Fig. 1.) They were held together only by the ridges on the exterior of the calculus. These ridges consisted of uric acid

FIG. 1.

with a trace of ammonia. The same substance in the form of a greyish-white deposit covered not only the exterior of all the calculi and fragments, but extended into the interior of the fissures, covering their sides with a granular or nodular layer. (Fig. 3.) Towards the outer extremities of the fissures, opposite the one or two outer concentric laminæ of the calculus, it was deposited much more abundantly, so as to constitute an obtuse wedge when seen in section (Fig. 2),

FIG. 2.

by the increase of which the fissure was opened. The fragments were, as a rule, more or less wedge-shaped, but convex externally when they corresponded to the exterior of the calculus, and concave internally when they had been lifted away from the nucleus. In some cases only one or two segments had been lifted out from a calculus. (Fig. 2.)

FIG. 3.

On the surface of the calculi the deposit often formed blister-like elevations, which might be perforated in the centre like volcanic craters. On section the upper wall of the blisters was seen to consist not only of this whitish-grey deposit, but also of fragments of the outer concentric laminæ of the calculus that had been upheaved by and remained embedded in it, and which were easily recognisable by their yellow colour and striation. When pressure was applied to a calculus with sufficient force to crush it the fracture took place not only by a separation between the concentric laminæ, but also at right angles to them, along what might be called planes of radial cleavage. The tendency to radial fracture could often be observed in the sections of calculi in museums, but it was best shown in the structure of artificial calculi as pointed out by Rainey in his book on Molecular Coalescence. We might, therefore, regard a calculus as an assemblage of pyramids arranged with their bases externally. In the case under consideration the new deposit of uric acid on the exterior had taken place in such a manner as sometimes to force up the outer laminæ and sometimes to open the inter-pyramidal sutures. When once an opening had been made between two pyramids the fissure spread inwards, the deposit acting as a wedge, so that the calculus became split in exactly the same way as a log of wood would be. The transverse section of an endogenous trunk presented many similarities to the section of a calculus. The pith answered to the nucleus, the annular rings to the concentric laminæ, and the medullary rays to the planes of radial cleavage. If a wedge were driven a short distance into such a log of wood parallel to its length and then pressed forcibly sideways it would lift a segment out of the trunk. The fissure between the woody fibres passed first inwards towards the pith, but when the wedge was pressed sideways the fissure turned off sharply at right angles and travelled in the line of the annular rings for a certain distance, but if the sideway pressure of the wedge were continued the fissure would turn upwards in the direction of the medullary rays and a piece of wood would be prised out. The process was identical in these calculi, the lateral pressure being caused by the wedge-like deposit shown at Fig. 2. Rainey showed in the work above mentioned that when the artificial calculi formed by the action of potassium carbonate on solutions of gum arabic were placed in denser solutions of the colloid than that in which they were originally formed they tended to disintegrate. This was just what had happened in the present case. The lower parts of the calculi were continually immersed in the pus-laden urine of the pocket, while their upper portions were bathed in comparatively pure urine.—Dr. ORD said he thought that the calculi found in the vesical sacculi could scarcely have been dropped into them like letters into the post-box. He thought that the disintegration did not depend upon concussion or upon the action of alcoholic or other preservative. That the lesion was a spontaneous fracture or disruption was shown in that it was an unconformable addition to a regular stratified formation. This might come about either in an explosive way, as he had shown elsewhere, or by more subtle disintegration from outside—e.g., by a change in the colloid which surrounded the calculus; or yet again there might be a gradual erosion of the surface from molecular disintegration. He was unable fully to accept the wedge theory which had been propounded by Dr. Plowright.—Mr. REGINALD HARRISON quoted Bigelow as stating that the human bladder could break two or more stones as the human hand could break two or more walnuts. Though this might, perhaps, be true in a limited sense, explanation must be sought in other directions. In the case related the bladder seemed to have been converted into a number of test-tubes in which these processes had gone on.—Mr. W. G. SPENCER inquired as to the nature of the force which split calculi from the outside. The instances shown reminded him of the splits in a cliff into which earth had afterwards fallen. A more exact statement as to the chemical composition of the different layers was desirable. The blistering which had been observed on the surface of the calculi was probably the first stage in the downward degeneration of their organic constituents, the ultimate result of the degeneration being carbonic acid and water.—Mr. BUCKSTON BROWNE said he had met with about half a dozen instances of spontaneous fracture of calculi, and they had always been found in cases in which the bladder was sacculated or in which there existed a post-prostatic pouch. The stones found in the latter place were often of semilunar shape, like a French roll, and were composed of a number of calculi which had undergone spontaneous fracture, and then became cemented together and moulded into an accurate cast of the pouch. The discovery that spontaneous fracture had occurred would militate as a point in favour of lithotomy as against lithotrity.—Dr. PLOWRIGHT, in reply, said that the stones were not moulded into each sacculus, but five or six of them lay loose in each pouch. Though crystals as a rule were

Digitized by Google

incapable of exerting any force, yet mortar and fine plaster could be split by crystallisation.

Mr. D'ARCY POWER showed a case of Primary Sarcoma of the Vagina associated with Multiple Polypi occurring in a child. The patient was aged two years and four months. She had suffered for fourteen months from a purulent vaginal discharge, and during the last five months from severe bearing-down pains. New growths had been observed in the vagina, and some of them had been removed by the practitioner who had charge of the case. The child was taken ill on May 20th, when she retched and had much abdominal pain. She had complete retention of urine for forty-eight hours, which was relieved by suprapubic puncture. She died with symptoms of uræmia on May 24th. Digital examination of the vagina during life showed that the entrance was blocked by greyish masses resembling œdematous granulation tissue, whilst the upper part of the vagina contained a tumour which was firmly adherent to its wall. It grew from the right side and from the posterior wall of the canal and extended as high as the finger could reach. The mass was cylindrical in shape and was very hard. An examination per rectum, however, showed that it infiltrated the recto-vaginal septum. The post-mortem examination showed that the vagina measured three and a half inches in length and two and a half inches in its transverse diameter. The mucous membrane was greatly congested. The middle and lower portions of its posterior wall were covered with pedunculated growths, some simple and gelatinous and others more solid and rounded. All the growths were covered with vaginal mucous membrane, and there was no ulceration except on the surface of those nearest the ostium vaginæ. A large mass of new growth entirely blocked the upper part of the vagina and was continuous with a perfectly circular tumour measuring two inches in its transverse diameter, which lay between the vagina and the rectum. Mr. Power said that the case was a rare one, but he had collected abstracts of twenty-five other cases which had been placed upon record by English and German surgeons. He deduced the following conclusions from a consideration of these cases. Primary sarcoma of the vagina in children was often associated with the presence of myxomatous polypi in the vagina. The polypi were recognised earlier than the sarcoma, for they grew nearer to the ostium vaginæ. The malignant growth was perhaps found more often upon the anterior than upon the posterior wall. It was therefore the rule for children affected with a vaginal sarcoma to suffer from retention of urine, whilst only exceptionally were the functions of the rectum interfered with. The growth did not disseminate, for the child generally died from the mechanical effects of the tumour before dissemination took place. The growth was generally a round or spindle celled sarcoma. The prognosis was in the highest degree unsatisfactory, as death had taken place in nearly every case. Operative treatment was most difficult even in the earliest stages, for the growth had a tendency to infiltrate the tissue between the bladder and vagina. The neck of the bladder was pressed upon, and the retention of urine could only be treated effectively by a suprapubic cystotomy.—The PRESIDENT remarked that in the case of sarcoma of the vagina which he had examined the bladder and urethra also contained growths, but there was no general dissemination. The structure in that case was a fibro-sarcoma.

Dr. WM. COLLIER showed a specimen of Multiple Polypi of the Stomach and Intestines from a young man aged twenty-one years, who was admitted to the Radcliffe Infirmary, Oxford, on June 28th last and died on July 12th. His illness commenced about twelve months previously with pain across the upper part of the abdomen and vomiting. The symptoms gradually increased in severity, and for some months before admission he had noticeably lost flesh and strength. The pain seemed not to be much affected by food, and on one or two occasions the vomit had been streaked with blood. When admitted the patient looked very pinched and ill. The tongue was covered with dark-brown fur. Nothing could be discovered on abdominal examination. While in the infirmary he vomited daily and often seemed to be in very severe abdominal pain; the bowels were constipated. He was at first fed on broth, milk puddings, bread-and-milk, and egg beaten up in milk; but on account of the pain a week after admission his diet was confined to four ounces of peptonised milk every second hour. On the evening of July 10th he was seized with pain of more than usual severity and the vomiting became more urgent. On the following morning his condition was evidently critical, the pain and vomiting had continued throughout the night, and the abdomen was becoming distended. A distinct tumour could be made out running obliquely downwards across the abdomen from right to left; it was dull on percussion. After consultation it was decided to open the abdomen and explore. On doing so a large intussusception was found and was without much difficulty reduced. In spite of this the patient's condition did not improve and about twenty hours later he died.

Mr. JACKSON CLARKE read a paper on Tertiary Syphilitic Lesions in Lymphatic Glands. He thought that tertiary syphilitic lesions were somewhat more common than was generally believed. He had recently observed an instance in an out-patient at the North-West London Hospital. A woman aged forty-two years attended for treatment from time to time for tertiary lesions of the skin, nasal fossæ, &c., and reappeared after an interval of unauthorised non-attendance in a condition of marked anæmia and complaining of lumps on the left side of the neck. These proved to be the deep cervical and axillary glands, which were as large as filberts and hard. At the time there were no active lesions elsewhere. The swellings rapidly subsided under iodide of potassium. He had only once observed gummata in lymphatic glands in the course of about 1000 necropsies. This was in the case of a man aged twenty-five years, who was admitted into St. Mary's Hospital, under the care of Sir William Broadbent, complaining of pain in the right side of the chest and in the right lumbar region. There were hæmaturia and slight fever. He had several attacks of pain in the right chest, accompanied by dyspnœa and collapse. He died in one of these attacks some days after admission. After death the right renal vein was found to be occluded by clot, the right kidney was enlarged, pale, and fibrosed, and it contained in the pelvis a circumscribed ulcer with raised edges. The right lung contained several infarcts. In the liver there were numerous gummata. The cervical glands, which had been noticed to be enlarged in life, were also found to contain gummata. In some cases there was a difficulty in distinguishing between syphilitic and tuberculous glands. As an instance Mr. Clarke mentioned the case of a child aged two years. When the patient first came under notice there was around the base of the glans penis a raised indurated sore. The history was that the child had been circumcised. All went well for four weeks, when the sore began to form. The lesion had been present for three weeks when the child was brought to the hospital. At this time there were, besides the sore, marked swelling of the inguinal glands, a general eruption of macules, papules, pustules, and some tense bullæ. There was also slight snuffling. The patient was treated with mercury for three weeks and the rash disappeared, but the inguinal glands continued to enlarge and began to soften. The glands were removed, and sections showed typical tuberculosis, with characteristic bacilli. In this case there might have been a mixed infection, but no exposure to syphilis could be traced.—The PRESIDENT said that these lesions were almost always overlooked. He had seen cases of cervical lymphadenitis in the out-patient department in which there was a history of syphilis and which were cured by the administration of iodide of potassium. Syphilitic glands were more indolent than tuberculous, were often doughy in places, and were more angular and less rounded. A mixed infection of tubercle and syphilis was not rare.

The following card specimens were shown:—

Dr. KANTHACK: (1) Dissecting Aneurysm; (2) Cylindroma of Large Intestine; and (3) Diffuse Primary Sarcoma of Liver.

Dr. VOELCKER: (1) Uterus Unicornis, with Congenital Malposition of the Right Kidney; (2) Epithelioma of Œsophagus invading the Trachea and Left Bronchus—Cystic Change in the Secondary Deposits in the Liver and Stomach; and (3) Ulceration of Large Intestine in a case of Enteric Fever.

Mr. TARGETT: Old Injury of Humerus from an Egyptian Mummy.

CLINICAL SOCIETY OF LONDON.

Cases of Excision of the Temporo-Maxillary Articulation in Children.—Sudden Death from Cardiac Syphiloma.—Traumatic Derangement of Knee-joint.

THE first ordinary meeting of this society for the present session took place on Oct. 11th, Mr. GODLEE, Vice-President, being in the chair.

Mr. ARBUTHNOT LANE read the notes of some cases of

Digitized by Google

Bony Ankylosis of the Temporo-Maxillary Articulation in Children which had come under his care, and on which he had operated with success. The first was a boy aged nine, the duration of the ankylosis being less than three years; the second was a girl aged twelve, and the duration less than two and a half years; the third was a boy aged four, and the duration less than three years; and the fourth was a girl aged ten, and the duration less than three years. He had also operated on a fifth case, the particulars of which he did not refer to. All these were cases of complete bony ankylosis, and the results obtained were most satisfactory, the wounds healing immediately, and a perfectly new joint developing very rapidly. Mr. Lane found considerable difficulty in taking away a sufficient quantity of bone in these cases owing to the vertical shortening of the ramus, due to a more or less complete want of development of the head and neck of the jaw, the upper and posterior portion of the ramus in old-standing cases becoming very broad and thick, and uniting over a considerable area with the temporal bone. He considered that the occasional failure of this operation resulted from an insufficiently free removal of bone.—Mr. HOWARD MARSH said that it would be of advantage to have these patients shown at a clinical meeting; he himself had had no opportunity of treating such cases in children.—Mr. F. C. WALLIS said he had helped Mr. Bloxam to operate on a woman aged thirty who had ankylosis of both temporo-maxillary joints, with consequent mal-development of jaw. Six months after the operation very good movement was obtained.—Mr. TARGETT said that a boy had been under his care with unilateral ankylosis of the jaw; there had been no history of otorrhœa. He found that simple section of the jaw gave no good result, and he had to excavate away the head of the bone. Movement at the present time was good, and the incisor teeth could be separated to the extent of an inch.—Mr. A. E. J. BARKER said that he had operated on two cases. The first, a girl aged fifteen, fell over the banisters and struck the lower jaw, complete ankylosis resulting, and the incisor teeth could only be separated for an eighth of an inch. He made a horizontal incision over the neck of the bone, chiselled away the head, and hollowed out a glenoid cavity. The second case was that of a child aged eight, and there was a scar over the region of the joint after disease of the ear. The joint was completely ankylosed, and the same operation was done. The result was good, the separation between the incisors being now more than an inch. In the older days before aseptic surgery ankylosis frequently followed the operation, because suppuration was permitted to ensue.—Mr. LANE, in reply, said that two of the cases had already been shown at clinical meetings of the society, and of the remainder one lived at such a distance from London that it was impracticable to bring the patient up for exhibition.

Sir DYCE DUCKWORTH read a paper on a case of Sudden Death due to Cardiac Syphiloma. The patient, a strongly-built man aged thirty-five, was walking in the street carrying a little boy on Oct. 7th, 1894, when he suddenly fell down and expired. The body was carried to St. Bartholomew's Hospital, and was examined on Oct. 9th. A very meagre antecedent history was obtained, which threw no light on the nature of the case. There was evidence of old syphilitic disease on the tongue and on the glans penis. A small gumma was found in the left lung. The heart weighed twenty-two ounces, and had firm adhesions to the pericardium both at the apex and at the base. The right ventricle was hypertrophied and dilated. The valves were natural. The left ventricle was hypertrophied and dilated. There was a round depression in its wall above the apex the diameter of a shilling, covered by long adhesions. This was due to a thinning of the wall, with much endocardial thickening. A large aneurysmal pouch was found behind the posterior cusp of the mitral valve. This appeared from without as a tumour growing from the base of the heart, completely covering the left auricle. Its walls were half-an-inch thick, and the pericardium was closely adherent over it. On section, the muscle was found to be replaced by tough fibrous tissue, with foci of gelatinous matter. The endocardium was greatly thickened and fibrous. Microscopic examination proved it to be gummatous in nature, with patches of caseation. The smaller arteries showed signs of endarteritis. These appearances indicated plainly a recent gummatous growth at the base of the left ventricle, and a similar, but older, one near the apex of that cavity. The fact of sudden death as a frequent occurrence in cases of this nature was alluded to, and it was pointed out that these clinical features were but little known and necessarily but seldom recognised. The morbid anatomy was well understood. He had collected particulars of fourteen similar cases. Death occurred almost, if not quite, suddenly in eight of these cases. The disease was rare in women, only one of the fourteen cases having occurred in that sex. The mean age of all the patients was thirty-two. Many of the cases appeared to have been previously devoid of urgent symptoms. In some there had been pericardial pain. It was pointed out that graver symptoms were to be expected when fibrotic changes followed on the evolution of the gummatous growths and when they led to aneurysms of the ventricular walls. The valves were usually not involved, and hence murmurs were not to be met with, as in the case of rheumatic endocarditis. The ventricles and their septum were the common sites of these growths. Tendency to fatal and sudden syncope was probably explicable by the fact that endarteritis affected the coronary arteries in part, and possibly by the occurrence of embolisms from the softening contents of aneurysms into coronary arterial branches, the ventricular walls degenerating in consequence and becoming gradually intolerant of strain. The great object was to make an early diagnosis when possible, and to seek for syphilitic concomitants in cases where there were obvious cardiac symptoms, such as palpitation or infrequency of pulse, hypertrophy, dilatation, &c., and no signs of involvement of the valves. The treatment was to employ iodide of potassium in full doses.—Dr. SIDNEY PHILLIPS said that he had collected a large number of cases and specimens. Two years ago he made a post-mortem examination of a patient who died in his chair with a newspaper in his hand. He had previously suffered from an acute attack of pain in the chest. He inquired whether, in the case under discussion, there had been a history of previous symptoms. In cases of cardiac gumma the patients were often found dead, but in all the cases in which he had been able to make inquiry there had been previous symptoms. In the instance above referred to the gumma was found in the left ventricle and near the apex of the heart, and this was the usual position of the lesion in the cases which caused sudden death. Cardiac aneurysm was a common complication, and he related a case to illustrate this—that of a young soldier who had suffered from syphilis and had been under treatment for four years, then came under treatment with an anginal attack which proved fatal. Syphilitic general fibrosis gave rise usually to dilatation and pseudo-hypertrophy.—Dr. HALE WHITE said that cases of genuine gumma of the heart were found to be rare at Guy's Hospital, only occurring once in several years; but syphilitic fibrosis of the heart occurred once a year—that is, 1 in 500 necropsies. He thought perhaps that a syphilitic affection of the heart might be diagnosed, but it appeared to him impossible clinically to draw a distinction between syphilitic fibrosis and gumma; if it yielded to treatment it would probably be a gumma. Of nine cases, six died absolutely suddenly, two of them being out-patients for pain and shortness of breath, while the seventh, eighth, and ninth cases were sufficiently ill to be in hospital at the time of their death. A series of cases collected by Dr. Fagge twenty years ago gave practically the same results.—Sir DYCE DUCKWORTH, in reply, said that more facts in the clinical history of these cases were required. He had lately been treating a case of hypertrophy of the left ventricle with palpitation and a history of constitutional syphilis within the last two years. Under treatment the patient had lost most of his symptoms.

Mr. BARKER described a case of Traumatic Derangement of the Knee-joint due apparently to fracture of the spine of the tibia, for which an exploratory arthrotomy was done. The patient received the injury while in a mine in South Africa, and came home quite disabled. In walking the knee was very insecure and inclined to give way inwards, which movement was accompanied by a sharp audible snap. The head of the tibia could be slipped backwards on the femur either by active or passive movement, but could only be replaced by hard pressure forwards. The nature of the injury seemed to be obscure, but it appeared possible that the spine of the tibia was broken off or the posterior crucial ligament torn through. The patient being anxious for an exploratory operation and relief, which only was considered possible, Mr. Barker laid open the knee-joint by sawing across the patella, and found the crucial ligaments apparently intact. The spine of the tibia was found, however, to be marked at its base by a deep groove, into which the handle of a scalpel could be

Digitized by Google

laid, and having the appearance as if it had resulted from imperfect union of a fracture of the process. Nothing further was done. The wound healed *per primam intentionem* and the limb was kept immobile for some months. When last seen, more than a year after operation, the patient had a useful limb, with none of the former abnormal movements. He was advised to be cautious in using it, however.—Mr. E. WILLETT asked what evidence was in existence that ligaments would contract when irritated.—Mr. GODLEE said that he had shown a specimen at the Pathological Society of the knee-joint of a boy whose leg had been crushed, and there was a large skin wound, necessitating amputation in the mid-thigh. On dissection of the knee-joint the spine of the tibia was found to be torn off. He had seen another case this year in a woman of small stature aged thirty, who had injured her knee in getting off a 'bus. There was no exaggeration of rotation of the tibia inwards or outwards, and she had been supplied with an apparatus for fixing the knee.—Mr. BARKER, in reply, held that if ligaments were irritated and the joint afterwards left at rest the ligament would shorten, as in stiff joints after inflammation, without intra-articular lesion.

HUNTERIAN SOCIETY.

President's Address.—The Infectiousness of Rheumatism.

THE first meeting of the winter session was held on Oct. 9th at the London Institution, the President, Mr. CHARTERS J. SYMONDS, being in the chair.

Mr. SYMONDS gave a short address on the Advisability or Justifiability of Explorative Abdominal Operations. His first postulate was that if we can feel sure that no serious additional risk is run by the patient through the operation, then it is not only advisable but practically imperative. This class of cases he illustrated by several examples of insuperable (by other means) obstruction. He next spoke of the possibility of serious risk brought on by operation, and this group he illustrated by a case of urgent symptoms induced by gut adherent to the abdominal parietes, in which rupture of the intestine during separation was unavoidable. A third group of abdominal operations he spoke of—viz., exploration with excision of a kidney—and laid down the inflexible rule that no nephrectomy should be done unless the other kidney had been definitely examined and found healthy. Lastly, he urged the great responsibility physicians now accepted if they waited till the bacillus coli communis had gained a firm footing in the tissues of the patient outside the lumen of the gut.

The PRESIDENT then called on Mr. F. R. Humphreys for his paper on the Infectiousness of Rheumatism.

Mr. HUMPHREYS referred to the recent lectures by Dr. Newsholme on the subject and to other writings. He then proceeded to give several illustrative cases in which skin affections, follicular tonsillitis of a somewhat special type, and acute rheumatism had seemed to him to definitely follow one another as if by infection, either in the same patient or in different members of the same household. He had taken careful notes of many such cases, and to him they seemed to point very strongly—though, he admitted, by no means conclusively—to the specific bacillary nature of true rheumatism.

Dr. SHADWELL gave illustrative cases in which he traced rheumatism to drain poisoning, and to the unwashed blankets in which a patient suffering from rheumatic fever had lain. He felt prepared to accept the infectious nature of the malady.

Mr. STEVENS hoped to see the specific bacillus found by scientific workers.

Dr. H. FOX thought it difficult to accept the bacillary theory, but drew attention to the relation or likeness of the tissues affected by rheumatism. His mind leaned more towards a nervous origin for the disease, quoting the historical case of the man who was cured of acute rheumatism by the shock of a railway accident.

Dr. LYON thought there was danger in accepting the bacillary view in that it might lead our minds too far from clinical causes—viz., lowering of the vital activity of the body with exposure—that, in fact, it might draw all attention to the seed, leaving the soil in a state of neglect.

Mr. J. T. FOX compared the possible bacillus to the malarial organism, and stated that, though malaria as a rule rendered the patient liable to future attacks, there was at least one variety that rendered the patient (he himself having experienced it) immune to future malarial paroxysms.

Mr. HUMPHREYS briefly replied, and mentioned a case in which from similar exposure to drain air the husband contracted typhoid fever and the wife acute rheumatism.

SOUTH-WEST LONDON MEDICAL SOCIETY.

Exhibition of Cases.

A CLINICAL meeting of this society was held at the Wandsworth and Clapham Union Infirmary on Oct. 9th, the President for the year, Dr. GILBERT RICHARDSON of Putney, being in the chair.

Mr. BREWARD NEAL, the medical superintendent of the infirmary, showed the following cases: 1. Sarcoma of the Axilla in a man aged forty-four years, following the removal of a warty growth from the wrist a year previously. 2. Progressive Muscular Atrophy in a man aged sixty-one years. 3. A case of old-standing Inguinal Hernia in which symptoms of strangulation came on half an hour after prolapse of the hernia. Failing reduction, and owing to the condition of the man (whose age was sixty-four years) becoming rapidly more urgent, operation was performed in two hours, with a successful result. 4. Chronic Rheumatoid Arthritis in a woman aged twenty-eight years, accompanied by vaginal discharge of a doubtful character. 5. A case of Foul Ulcer dependent upon Diseased Metatarsal Bone, which was successfully excised, leaving only a small sinus. 6. Two cases of Senile Scirrhus of the Breast.

At the conclusion of the evening a hearty vote of thanks was passed to Mr. Neal for his courtesy and hospitality.

READING PATHOLOGICAL SOCIETY.

Inaugural Address.

THE fifty-fourth annual meeting of this society was held in the library of the Royal Berks Hospital on Oct. 9th, the President, Mr. OLIVER C. MAURICE, being in the chair.

Dr. STEPHEN MACKENZIE, physician to the London Hospital, gave the inaugural address of the session, a most valuable discourse illustrated by numerous drawings, on the advantage to be derived from the Study of Dermatology. He said the study of diseases of the skin had not hitherto met with the attention the importance of the subject demanded, although every practitioner met with cases of which it was important he should have an accurate knowledge; besides which it afforded one of the best fields for educating the observant faculties and training the mind to discern the phenomena of disease and for watching the effects of remedies. Nowhere else, with the exception of the visible mucous membranes, could he observe the whole pathological processes so well. He described the skin physiologically and the influences affecting it, and then dealt most exhaustively with the many diseases to which the epidermis is liable and with their treatment. A few of his conclusions may be briefly stated, such as that many skin diseases generally believed to be constitutional were traceable to bacteria, and that very few skin diseases were directly traceable to dietetic causes, though improper diet might largely aggravate existing eruptions, so that the avoidance of alcohol, the regulation of the bowels, and the cure of anæmia were of infinitely more importance in treatment than diet; at the same time, the disease must be cured by external means. The golden rule by which to preserve a healthy skin, as well as to avoid various ills, was to observe regularity, moderation, and temperance in matters of eating and drinking, especially as regarded alcohol.

The lecturer was heartily thanked in the name of the society by Dr. Shettle for his most valuable address, the vote being carried by acclamation, and thanks to the President concluded the meeting. Later the annual dinner was held at the Queen's Hotel, Reading, under the presidency of Mr. O. C. Maurice.

WIGAN MEDICAL SOCIETY.

The Clinical Value of Inoculation Experiments in Guinea-pigs in the Diagnosis of Tuberculous Phthisis.

A MEETING of this society was held on Oct. 3rd, when a good number of members were present, and several visitors

Digitized by Google

from Preston and St. Helens. Mr. WM. MITCHELL ROOCROFT, President, occupied the chair.

Dr. T. HARRIS read a paper on the Clinical Value of Inoculation Experiments in Guinea-pigs in the Diagnosis of Tuberculous Phthisis. He referred to the difficulty which existed in diagnosing between some cases of simple chronic pneumonia of a non-tuberculous nature and chronic tuberculous fibroid phthisis. He brought forward a series of cases which he had met with during the past two years where the sputum had been repeatedly examined by himself and other observers for tubercle bacilli with negative results, and the sputum from these cases he had inoculated into guinea-pigs without producing tuberculosis. He also referred to some cases where the expectoration was fetid and was due to bronchiectasis, and where tubercle bacilli were absent from the sputum. The sputum from these cases, which had also been inoculated into guinea-pigs, gave negative results. A third series of cases were those of repeated examinations of the sputum from cases which had failed for a long time to show tubercle bacilli, but where, after a number of examinations had been made, a few of the organisms were discovered. In all these latter cases the guinea-pigs which were inoculated with the expectoration became tuberculous. The experiments were considered of value as check experiments where repeated examinations of sputum from doubtful cases of pulmonary disease failed to show the presence of tubercle bacilli, and they also confirmed the view that chronic fibroid disease of the lung, usually left by an acute pneumonia, does exist and that such cases are of a non-tuberculous nature.

BRADFORD MEDICO-CHIRURGICAL SOCIETY.

President's Address on Otorrhœa.—Venesection in a case of Puerperal Eclampsia.—Exhibition of Cases and Specimens.

AT a meeting of this society held on Oct. 8th Dr. S. JOHNSTON, the retiring President, introduced Dr. Adolph Bronner as the President for the coming year.

Dr. ADOLPH BRONNER then delivered his presidential address on Otorrhœa, its Complications and their Treatment. Otorrhœa was the result of an inflammation of the mucous membrane of the middle ear caused by micro-organisms passing up the Eustachian tube from the pharynx; hence the importance of examining the throat in these cases. The difficulty of draining the tympanic cavity and the care to be used in syringing were next alluded to. In children otorrhœa is very common, 85 per cent. being the result of one investigation. The principal complications of otorrhœa are:—1. Granulations, which are to be touched with chromic acid or with ferric chloride. 2. In polypi the cold snare is generally used to remove these growths, attention being directed to the importance of dragging out the polypus by its roots. 3. Caries of the ossicles, removal of the ossicles being required in some cases. 4. Cases of disease of the attic, of the mastoid antrum, and of the mastoid cells were described. Clinical charts and pathological specimens were handed round illustrating the treatment of these complications. The different operations for mastoid diseases which are associated with the names of Swartze, Macewen, Koster, Bergmann, and Stacke were described. 5. The symptoms of brain abscess, either cerebral or cerebellar, were discussed, and Dr. Bronner detailed a case on which he had recently operated. The patient, aged thirty-three years, had been deaf on the left side for thirteen years. Eleven years ago she had two polypi removed, and since then had had a constant otorrhœa. When seen by Dr. Bronner the symptoms were earache, pain in the head, a small quantity of discharge from the left ear, mental confusion, slow pulse, and constipation. Dr. Bronner trephined one inch above the external auditory meatus, and with a trocar found pus. A drainage-tube which was inserted at the time of the operation came out on dressing the wound a few days afterwards and could not be replaced. In a few days pressure symptoms came on, necessitating drainage through the tegmen tympani. The patient then made an excellent recovery. 6. The symptoms of thrombosis of the lateral sinus are rigors, fever, vomiting, and œdema over the mastoid process, which is painful on percussion. The chief danger is pulmonary pyæmia. The treatment recommended was turning out the thrombus and plugging with boric acid. Some surgeons (Ballance and Lane) advocated tying the internal jugular vein in addition. 7. Many cases of local meningitis had been successfully treated by trephining and drainage. Cases were cited illustrating the different complications of middle-ear disease, and the instruments used in the operations arising therefrom were exhibited. The conclusions Dr. Bronner would direct attention to are: (1) the frequency of these diseases in infancy; (2) the necessity for operation; (3) the mastoid process should be carefully examined, and even if there be no external signs of disease the operation should be done if symptoms be present; and (4) the mastoid antrum should be opened before trephining.

Mr. MERCER read a paper on Venesection in a case of Puerperal Eclampsia. A patient in the eighth month of pregnancy was in convulsions; she was comatose and dropsical; the urine on boiling became solid. One-third of a grain of pilocarpin was given hypodermically, chloral and bromide were administered by the rectum, and a tent was introduced into the os uteri. Later chloroform was administered, and delivery was accomplished by the aid of forceps. After delivery the fits returned and were not controlled by treatment. Thirty ounces of blood were taken from the arm; the patient became conscious, had no more fits, and made an uninterrupted recovery.—The paper was discussed by Dr. A. Bronner, Dr. Goyder, Dr. Bell, and Dr. Gray, and Mr. Mercer replied.

Mr. WILMOT showed a man suffering from Lymphadenoma affecting the axillary, cervical, and inguinal glands.

Microscopical specimens were exhibited by Dr. MAJOR and Dr. CHAPMAN.

NORTHUMBERLAND AND DURHAM MEDICAL SOCIETY.

Exhibition of Cases and Specimens.

THE annual general meeting of this society was held on Oct. 10th. Dr. JAMES DRUMMOND of South Shields, the newly elected President, was introduced to the chair.

Mr. WARDLE showed a patient on whom he had successfully operated for Diffuse Suppurative Peritonitis due to disease of the appendix. The abdomen was drained of two quarts of pus, and the appendix, though seen, was not removed on account of the critical condition of the patient. The drainage-tube was taken away at the end of forty-eight hours, and except for some fæcal discharge through the tube opening on the sixth day healing was uninterrupted. Mr. Wardle thought that in such cases the tube might be removed earlier than had been taught.

Mr. RUTHERFORD MORISON showed some cases of Syphilis, and Mr. PAGE a case in which Epithelioma of the Penis and Inguinal Glands had been mistaken for a syphilitic lesion.

Dr. D. DRUMMOND showed a man forty-eight years of age who had been troubled with a cough for two years. In the early stages of his illness all the signs and symptoms of tuberculous consolidation of the right apex were present, and the case was regarded as one of phthisis pulmonalis. During the last two months severe pain in the back, chest, and right arm had been the most prominent symptoms, and still more recently an enlarged gland was discovered under the left jaw. The gland was now very hard and fixed, and this, together with the severe pain and other signs of a growth in the anterior mediastinum, made the diagnosis of malignant disease of the lung easy, though the long history and the physical signs at first proved misleading.—Dr. DRUMMOND also showed a neurotic young man aged twenty-five years who had been lying in bed for five years and was reduced to the weight of 5 st. He was a very good example of the condition known as anorexia nervosa. The patient after a month of treatment has gained a stone in weight and is walking about. For the first fortnight of his stay in hospital, however, he did no good, and not until the nurse was forcibly impressed with the need of his getting well did any improvement result. The case illustrates two things—first, that a certain amount of compulsion must be used in such cases; and, secondly, that isolation was not essential.

Dr. HUME showed a boy aged fourteen years, together with a Tumour and his Upper Jaw, which he had excised. The history of the case was interesting, for four years before the patient received a blow on his left cheek which swelled immediately. The swelling soon became painless, but slowly

Digitized by Google

increased, and was removed on Sept. 2nd by the ordinary operation for excision of the upper jaw. Microscopically the tumour was a myeloid sarcoma.—Dr. HUME also showed a man on whom he had successfully performed Nephrectomy for what he regarded as a rare condition. The man was twenty-nine years of age. Five years ago he had his leg amputated for accident, and retention of urine, which followed, necessitated the use of a catheter. The catheter caused cystitis, and from this time he had urinary distress. Pain in the right kidney with pus in the urine suggested calculus, and the kidney was examined by drawing it out to the loin through the ordinary lumbar incision and palpating it, but it was neither incised nor punctured. Dr. Hume thought the danger of wound infection from puncturing even a healthy kidney was to be remembered. No calculus was discovered and the kidney was returned. For some months the patient was no better and no worse. Then the pain became more severe, and at last a swelling was discovered in the loin, evidently an enlarged kidney. Nephrectomy was performed on July 15th, 1895, after which for a time the urine was free from pus, but then there was some return. The patient's general condition was much improved. On section the kidney was found to be enlarged and studded with abscesses, and looked as if it might be tuberculous. The microscopist reports, however, that it is an example of ascending septic nephritis.

Dr. WARDLE exhibited a very large Gall-stone removed by Cholecystotomy from a woman over seventy years old. There was a history of frequent "spasms," but except for the absence of jaundice all the evidence was in favour of gall-stones. After a very severe attack, threatening life, cholecystotomy was performed. The gall-bladder walls were very thin and were firmly adherent to the stones, which had to be dissected out. Death followed from senile heart.

Dr. HUME exhibited a Myoma from the anterior vaginal wall of a middle-aged unmarried woman. Hæmorrhage was severe and frequent attacks of retention of urine called for the use of the catheter. The urethra was so elongated and tortuous that considerable difficulty was experienced with the catheter, and on one occasion the bladder had to be aspirated. The growth projected from the vulva, protruded the urinary meatus, and filled the whole vagina. It was enucleated after division of the vaginal wall, and the bleeding, which was severe, was arrested by tamponning. Dr. Hume could find no such growth described as a fibro-myoma of the vaginal wall.—Dr. HUME also showed an Inverted Uterus removed by Vaginal Hysterectomy. The inversion followed confinement four years before. Packing with iodoform gauze and different forms of elastic pressure were ineffectually tried before hysterectomy was performed. The patient made a good recovery.

Dr. MURPHY showed a Tongue excised for Epithelioma from a woman. The sex of the patient was of interest.—Dr. MURPHY also showed a Pessary of Indiarubber, filthy and corrugated, which had lain for years in the vagina of a patient supposed to be suffering from cancer.—Dr. MURPHY likewise showed an Enlarged and Cystic Ovary and a Normal Ovary and Tubes which he had taken from a patient without a vagina and with a nodule only to represent the uterus, who had suffered severely from abdominal pains.

Dr. D. DRUMMOND showed Congenital Cystic Kidneys taken from an adult. The case was correctly interpreted during life from the presence of uræmia and of symmetrical swellings of long duration in the renal region. The specimens were beautiful examples of the condition.—Dr. DRUMMOND also showed an Aneurysm of the Aorta which had pressed upon and obstructed the right bronchus. He had shown the patient at a previous meeting, and now exhibited the specimen obtained post mortem, for in connexion with it he had observed what he ventured to call a new physical sign. The respiration was stertorous. Over the right lung inspiration was loud and accompanied by rhonchi, as over the left, but in the right lung expiratory sounds were absent. That this was due to pressure on the right bronchus the specimen exhibited made certain.

LITERARY INTELLIGENCE.—The Queen has been graciously pleased to accept the dedication of an Indian translation of Mr. Samuel Osborn's book, "First Aid to the Injured." This book now appears in six languages—English, French, German, Italian, Japanese, and Hindustani.

Reviews and Notices of Books.

Medical Gynæcology: a Treatise on the Diseases of Women from the Standpoint of the Physician. By ALEXANDER J. C. SKENE, M.D., Professor of Gynæcology in the Long Island College Hospital, Brooklyn, New York, &c. With Illustrations. Edinburgh and London: Young J. Pentland. 1895.

DR. SKENE tells us in the preface that the present work has had its origin in a consciousness on his part that the science and art of medicine and surgery should be above all party questions, and that those who place a just estimate on both branches of the healing art and employ them without predilection and prejudice are the most successful and reliable. He holds that unreasonable devotion to either medicine or surgery is wrong. No doubt, as he says, there have been some who have been inclined to push the surgical treatment of the diseases of women to extremes, to the neglect of medicine; and, on the other hand, physicians who have had too much confidence in medicine and have occasionally failed to do their patients full justice. We are quite in accord with Dr. Skene as regards his temperate and judicial views on this matter. They might be studied with advantage by those who have taken extreme views one way or the other on this question. The work is divided into three parts. Part I. has to do with the primary differentiation of sex, development and growth during early life, and the conditions favourable to the evolution of normal organisation. The main object of this part of the book has been to consider the various means that best conduce to the development of a vigorous constitution. Part II., which comprises the largest portion of the work, deals with the characteristics and diseases of the active period of life, and Part III. with the phenomena connected with the transition from middle life to old age, and the diseases more especially likely to occur at that period. There is a good deal of information on the uses of electricity in gynæcology, on massage, on diet in disease, and on mental therapeutics. There is a useful chapter on unnatural habits, in which the author describes (1) the Invalid Habit and (2) the Opium Habit. The former is well defined as a singular perversion of life, mental and physical, seen among women who insist upon being invalids while there is nothing discoverable the matter with them. He distinguishes between this condition and hysteria and neurasthenia, though we must admit the task of separating them clinically seems to us a matter of the utmost difficulty. Dr. Skene does not believe in massage and electricity for the cure of the "invalid habit." In his opinion, the only effectual treatment is by means of "the occupation and exercise cure"—in other words, by voluntary coöperation on the part of the patient. We think there is a great deal of truth in the views here expressed. As regards the opium habit, no doubt, as the author thinks, the foundation of it is often laid in the use of opium after operations. He has found opium of great use in controlling excessive sexual desire, it being in this respect far superior to the bromides. The opium habit in his experience has sometimes been found to induce amenorrhœa. In making a diagnosis of the opium habit Dr. Skene lays stress on the temperature: it rises when the opium is withdrawn—sometimes to as much as 103·5° F.—and falls when the opium is given again. With respect to the treatment of this habit, he thinks the gradual abandonment of the drug is the only rational and safe plan.

A noticeable feature of the book is that there are very few illustrations. We have read it with much interest, and consider that it contains a great deal of useful information on the more especially medical aspects of gynæcology.

Fonti ed Estensione del Diritto Sanitario. Dal Professore CARLO RUATA. Città di Castello. 1894. (*Sources and Extension of Sanitary Law.* By Professor C. Ruata.)

THE able and energetic occupant of the chair of Materia Medica in the University of Perugia has contributed more than one substantial work to sanitary literature. His treatise on Public Hygiene, favourably reviewed in THE LANCET, was but the prelude to other achievements in the same field, the last of which, embodied in the publication before us, yields to none of its predecessors in scientific importance or expository skill.

Professor Ruata is deeply impressed with the saying of one of the founders of young Italy, Massimo D'Azeglio, the successor of Cavour, "L'Italia è fatta; facciamo gl' Italiani" (Italy is made; let us make Italians); and to the end thus indicated he seeks to lead up by infusing into his compatriots a more vital and more effective "sense of citizenship" than they seem to possess. He finds them, above all things, deficient in that "public consciousness" which inspires combined and consentaneous effort in face of the thousand-and-one maladies which decimate the people—that spirit of sacrifice which makes a man exert himself not so much for individual safety as for the common weal. He points, in proof of the lack of this spirit, to the mode in which zymotic disease is generated and diffused, and demonstrates, with detailed narrative and convincing logic, how Italy loses thousands of lives annually for want of that wise altruism which sees in the good of one's neighbour the conditions of personal salvation. The man who by culpable neglect, *a fortiori* by set purpose, contributes to the vitiation of the atmosphere, for example, sins against a hygienic right, that of respiring pure air, which is the appanage of the humblest as of the highest; so that it is the duty of the State to enforce observance of the law, protecting that right when neglected, and to punish its violator when caught in the act. Above and before all administrative or penal enactment, however, comes the education of the individual, firstly, in that knowledge which underlies all other, the knowledge (in the late Sir James Coxe's oft-quoted phrase) by which every citizen "becomes the intelligent custodian of his own health"; and, secondly, in that principle, expressed for all time by the great English poet, which makes "all men's good each man's rule." Very instructive as a vindication of these positions is Professor Ruata's account of the fearful ravages of small-pox in Sicily during the years 1888 and 1889—an object-lesson in public health which ought, in view of the perennial anti-vaccination conflict raging in Great Britain, to be made *publici juris* in an English translation. So also is his re-enforcement of a warning once and again given forth in our columns in the matter of serotherapy and diphtheria—a warning against the tendency of the most approved therapeutic measures to supersede sanitary effort. "Sanitary law," he says most aptly, "not only does not want deaths from diphtheria, but it does not want patients from the disease; it, therefore, distrusts those palliatives which serve to keep the population in that fatal lethargy in which it is always content to lie with regard to preventable maladies." Not less opportune, particularly in Southern Europe, is his exposition of how atmospheric and aqueous contamination is to be guarded against by the conversion of mediæval into modern cities, as in Turin, where the widening of streets and the knocking down of rookeries have lowered the mortality from 32 to 20 per 1000.

The whole treatise forms a vivid and impressive introduction to the study of sanitary law, on which, indeed, Professor Ruata delivered a memorable series of lectures before the Perugia School. For not a little of his detail or illustration he avows himself indebted to the "più autorevole giornale di medicina esistente" (the most authoritative of existing journals of medicine), as he is pleased to call THE LANCET. But neither that indebtedness on his part, nor the sense of compliment on our own, need affect our judgment of his treatise or our deliverance on its merits, worthy as these are of an author whose hygienic achievement has approved itself not only to Italian schools but to those in both hemispheres.

Le Moyen Age Médical: les Médecins au Moyen Age; les grandes Epidémies; Démonomanie; Sorcellerie; Spiritisme; la Médecine dans la Littérature du Moyen Age; Historiens; Poètes; Auteurs dramatiques. Par le Dr. EDMOND DUPOUY, Ancien Interne de Charenton et des Asiles d'Aliénés; Lauréat de la Société Médico-psychologique; Prix Esquirol et Prix Aubanel. Paris: Société d'Éditions Scientifiques, 4, Rue Antoine-Dubois. 1895.

THE first section of this interesting volume is devoted to "Les Médecins au Moyen Age," commencing at the fourth century of our era, when Western Europe, invaded by the barbarians, witnessed the flight of men of science and letters to that famed Alexandria which was for a certain time to become their home. Medicine, however, made but little progress in these early times, until in the year 805 the Emperor Charlemagne "decreed" that it should be added to the studies of the schools. The laws of Théodoric, observed up to the eleventh century, were not, however, calculated to make the science or practice of medicine popular. Amongst the curious laws of that period a surgeon was to receive "cinq sous pour l'opération de la cataracte grise." Reform, however, came at last, in 1206, by the foundation of the University of Paris, which comprised a Faculty of Medicine and numerous students, many of whom became men of mark. From that period progress became slow, but steady, up to the time of the foundation of the College of Surgeons of Paris in 1271. This part of the work contains many classical and interesting quotations. That professional services then as now were not always appreciated is proved by the following lines:—

"L'élève d'Hippocrate en sa pénible étude
Est trop souvent payé de noire ingratitude."

The remarks on Baths and Bathing are amusing and copious; there are also long extracts from the writings of Montaigne. The second section, "Les Grandes Épidémies," treats of La Peste, La Peste Noire, Le Mal des Ardents, Les Fièvres Éruptives au VIe Siècle, La Suette d'Angleterre, Le Scorbut, La Lèpre, and La Syphilis. Each of these subjects is treated at considerable length, occupying in all over seventy pages.

The third part is entitled "La Démonomanie au Moyen Age." Commencing with the appearance of the spirit of Æsculap counselling Galen to bleed for an attack of pleurisy, we pass to Soranus, who had recourse to magic chants as remedies; whilst later in the thirteenth century a *pater noster* and other prayers were recommended for fractures of the bones. The description of the Épidémie of Sorcellerie in Artois in 1459 is extremely interesting. This is followed by numerous examples of hallucinations, of intercourse with demons, and painful descriptions of the burning of thousands of the unfortunate victims of the fanaticism of the period. To the credit of the profession of these dark ages be it said that many of its most enlightened members vigorously opposed these brutalities.

"L'Hystéro-Démonomanie des Cloîtres" forms a separate chapter and is worthy of much attention. This is followed by an article of great interest on "Hystérie et Force psychique," which deserves to be studied.

It is not a little agreeable to pass from such serious subjects as are presented in the preceding portions of this work to the concluding part, entitled "La Médecine dans la Littérature du Moyen Age." In this part the author, considering that it is in the writings of the poets and dramatic authors of an epoch that the fullest appreciation of the medical ideas of that time are to be found, makes liberal illustrative quotations from the poems, plays, and farces of the Moyen Age. The work throughout forms a record of great value, and affords ample evidence of the varied and untiring research of the learned author.

THE LANCET.

LONDON: SATURDAY, OCTOBER 19, 1895.

THE humanity of the medical profession is not often called in question. When it is so we feel it our duty to look at the facts. A letter in the *Western Daily Mercury* headed "The Medical Profession and Humanity," and signed by HENRY IVEY of Broad Oak, furnishes such an occasion. Mr. IVEY permits himself to say or to imply that in three cases of accident in his own neighbourhood the attention of medical men to serious accidents was hesitating or slow, and that the consequences in two out of three cases were fatal. In the first case a boy was injured. The medical man applied to demurred to going to the accident on the ground that he was not the attendant of the employer. He went when it was shown that he attended the boy's family. In the second case a boy was torn with a threshing-machine and was bleeding. The first medical man applied to declined to go as the messenger could give no assurance as to the payment of the fee. A second was seen and required some responsible person to be found before he would attend. Delay was occasioned and the sufferer died. In the third case a party were travelling home at midnight in a trap when the shafts broke, and two persons were badly injured, of whom one died. One practitioner called (at midnight) declined to attend on the ground that he was not the family surgeon. Such is the burden of the statement of Mr. HENRY IVEY of Broad Oak. We have no right to question its accuracy, but we should remember that it is a one-sided statement, and it is very probable that if the medical version of these facts were given it would differ materially from the one before us.

It is no part of our inclination or of our duty to apologise for any want of humanity in medical men when it is really established. The broad reputation of the profession in this respect is too precious for us not to be jealous of any instance to the contrary that might seem to tarnish it. But it is our business to press two or three considerations—not for the first time—that seem to be overlooked by men like Mr. IVEY. They are apt to assume that all accidents are grave ones, and that the medical man who hesitates about rushing to them knows them to be such. This is a great mistake. Under the head of accidents medical men are summoned at all hours to incidents which are not grave and which can afford to wait for the regular attendant of the persons injured, whose presence is always an advantage to the patient. Accidents figure very largely in the eye of the public, but they do not figure so seriously in that of the profession. They are only a part of the great field of medical duty, and in rushing to them a medical man may be leaving more important duty. Mr. IVEY says: "Accidents suspend the common rules of life with all classes *save one*." This is as ungenerous as it is unjust. For all the centuries the public have left members of the medical profession to look after accidents with scarcely any provision for their being rewarded. Our profession has had to do all "the humanity." And it has done it so spontaneously, so uncalculatingly, that the public have come to think it is bound to do it, and to do it for nothing. It is an everyday experience that while there is a competition to rush for the medical man in cases of accident, there is a common consent of neglect to see that he is remunerated, and very often a repudiation of responsibility, more marked in those who have been most eager to demand his immediate attendance. It is really the public who are at fault in this matter. And if Mr. IVEY had taken occasion to read the public a lesson on this subject he would have been better advised than in lecturing members of the profession on what he is pleased to call their "caprice."

The Samaritan service that is rendered to the public by the profession in all its ranks is enormous. Medical men are never safe. We have known in the holiday season which has just closed and in other seasons the most striking instances of medical men, at great personal trouble to themselves, acting the part of the "good Samaritan." But this is nothing compared with the "good Samaritan" part played by the practitioner in a poor neighbourhood, who is at the mercy of every accident, many of which are occasioned in discreditable ways and happen when the public are in bed. Mr. IVEY himself has an inkling of the truth in this matter. "I do not say that in any case gentlemen of the faculty should be placed at the 'people's caprice' with no rights of their own to observe." But this is very much the contention of Mr. IVEY'S letter. In some other countries there is provision made at the public expense for services of emergency such as the profession is constantly called on to perform. Before medical men can be regarded as public servants it must be shown that the public have engaged them to act and have discharged their own duty. Meanwhile, without judging particular instances on imperfect data, we feel sure that medical men as a class will not be found wanting in those sentiments of humanity which have always been strong in the profession. There is something in the very nature of our duties which exposes us more than other men to unreasonable and untimely demands on our time and on our very health and life. The public have been somewhat demoralised by the ready way in which our help has been always given. This demoralisation must be checked, but in checking it the profession will not generally fall into any great error of selfishness.

IT was a favourite axiom of the late Sir ANDREW CLARK that chronic diseases — always excepting those which arise from external agencies or inherited defects— are in the main dependent upon violations of "physiological laws." That may have seemed a broad and sweeping statement, yet the more such diseases are studied the truer does the axiom appear. In itself, perhaps, the idea embodied in this phraseology had nothing especially novel or striking. Its merit lay rather in its application—an application which this sagacious and experienced physician never wearied of enforcing. "Return," he would say, "to the ways of physiological righteousness and you will be healed." The advice was easily given, but to follow it in its integrity must often have been exceedingly difficult to the patient

Digitized by Google

Yet it was practical and rational, and were it not for the highly artificial manner in which lives are spent, or for the restricting influence of habits that have become a second nature, it might not have been so arduous to follow. The underlying principle seems to be this—that in diseases there is a disturbance of the physiological mechanism; the organism works with discomfort; and there is nothing for it but to alter the conditions if we wish to restore it to sounder action. The law may not have been consciously transgressed; on the contrary, from some defect in the natural interchanges between blood and tissue, in perverted metabolism, imperfect elimination, or what not, the apparatus itself may have got out of gear, and unless rectified the change, both functional and structural, may become permanent and dangerous to life itself.

The art of medicine consists, not in a direct attack upon the lesion or the forcible expulsion of peccant material, but rather in the rendering of aid to the natural forces, by whose operation alone can the restoration be effected and the disease, as we say, "cured." The time has long gone by when the former doctrine obtained and when the treatment of disease was dominated by fantastic notions upon the nature of morbid processes. Now, however, whether we admit it or not, we are in all our practice dominated by a strong belief in the all-sufficiency of the powers of nature to repair injury or restore function, provided that they are enabled to exert themselves. Nor does this apply to such obvious remedial measures as the enforcement of rest, the removal of noxious influences, or the reinforcement of vital power by careful dietetic rules. It embraces the whole sphere of therapeutics, for even the administration of drugs is, or should be, directed to the same end. If we cling to the alternative view that medicines act in some special manner, each one appropriate to a particular derangement, it is because of imperfection of knowledge and the thraldom of tradition. That diseases owning a specific origin from the introduction from without of a parasite or virus are to be successfully combated by specific drugs or antidotes, if only we could find them, cannot be gainsaid. But it is different with the large group of disorders due to defective mechanism, perverted secretion, or irregular metabolism. The initial factor in many such affections is often absolutely unknown; no doubt it has been some violation of physiological law—but how or in what direction it seems futile to inquire. The declared disease, that which we are called upon to treat, presents us with the pathological results of the vicious action, and the only hope for their removal rests in changing the whole nutritive conditions, and thus perchance restoring the normal physiological activities. There is a large class of maladies in which such efforts might at first sight seem doomed to failure. These are those which depend on tissue degeneration and the accumulation of its effete products. But when we reflect that life consists in an alternating cycle of degeneration and repair, we become aware that there are in the living organism itself the ways and means for removal of dead matter and the production of new living substance. There is no fixed limit to the recuperative powers, and all treatment must have for its aim their support and excitation.

This mode of viewing therapeutics is more hopeful than that which relegates degenerative changes, particularly those involving vitally important organs, to the class of irremediable affections. Much has been done by the recognition of this fact in the treatment of chronic heart disease, especially those forms in which there are muscular failure and degeneration. The extension of the same principle even to so admittedly hopeless a lesion as arterial atheroma was expounded in these columns last week by Dr. LAUDER BRUNTON with his customary lucidity and wealth of physiological examples. The means he suggests are simple, but they have a rational basis, and they are founded on the facts of physiology as well as on a firm faith in the *vis medicatrix naturæ*.

A CASE under the Lunacy Act of very considerable importance both to the profession and to the public was concluded at the Birmingham Quarter Sessions on the 11th inst., the prosecution having been undertaken at the instance of the Treasury. It was alleged that the defendant, a surgeon practising in Birmingham, had unlawfully taken charge of Mrs. JOHNSTON, a lunatic, and kept her at his residence, an unlicensed building, without an order from the judicial authorities. It was further alleged upon the indictment that the defendant had used unnecessary mechanical means of bodily restraint, and that he had not kept a record of such restraint as prescribed by the statutes. Mrs. JOHNSTON was the widow of a surgeon who left her a large income under certain restrictions. It was stated that, on becoming a lunatic, she was handed over to the defendant's care to prevent the trustees under the will retaining her income and using only such portions as were necessary for her maintenance. Her detention came to the knowledge of the lunacy authorities, and she was removed to the asylum, where she died within twelve days. The defendant disclaimed any intention to do wrong, though admitting technical offences. He declared that he was actuated by higher motives than gain, and that what he did was in the honest belief that it was the best thing for his patient. The Recorder, in summing up, said he could not see how there could possibly be any defence to the first and third counts, charging the defendant with detaining Mrs. JOHNSTON and not keeping a record; while the second count—that of using mechanical restraint—was the most serious. It was hard to think, he added, that the medical man was unaware of the fact that the woman had been out of her mind before and that her husband in his will had given directions as to her maintenance in the future should such symptoms again manifest themselves. The jury returned a verdict of "Guilty" on all three counts. The Recorder stated that he had great difficulty in arriving at a conclusion as to what punishment he should inflict to vindicate the law. He was willing to admit that the defendant acted upon an honest but ignorant belief, and therefore decided to impose a fine of £50.

The case is an important one because it illustrates in itself many of the points that arise day by day in

Digitized by Google

connexion with the question as to what is the proper mode of providing for and treating insane persons who have independent incomes. It also demonstrates the difficulties which the law has to deal with in lunacy cases of the sort where any question of honest ignorance arises. The gravamen of the charge does not lie altogether in what was actually done by the defendant to his patient, for she no doubt required asylum treatment, and it is not beyond possibility that some amount of mechanical restraint might for a time be needed. To our thinking the most serious feature of this particular case, leaving out of the question the higher motives and honest beliefs of the defendant, rests upon the "ignorance" that was relied upon for the defence. If a medical man has not a knowledge of the law in a matter of the sort it is not to be expected that he would feel it to be his duty to make himself acquainted with the principles which govern the use of mechanical restraint or to see the necessity for recording the fact that it has been used. Without wishing to dwell at any length on this aspect of the case, we are anxious to point out that the treatment of single paying patients in private houses, whether of medical or lay members of the community, is not in itself either harmful or undesirable; and the law, accepting this view, makes the needful provision for it and has to see that the statutes and regulations for safeguarding the interests of the patients are duly carried out.

It is always a pity when public mistrust of the medical dealing with lunatics is accentuated by the avoidance of the necessary preliminaries, which are neither expensive nor complicated. When these preliminaries have been arranged and the patient certificated, the rules for after-guidance in the official treatment of the case are simple enough; and it seems to us that acquaintance with the requirements of the law is dearly purchased, as in the present instance, by the infliction of a fine or the possible risk of imprisonment. Ignorance of the law is the last thing that should be pleaded. Those who dislike wading through the technicalities of Acts of Parliament will find plenty of explanatory works which bring the requirements of the Lunacy Act of 1890 within easy grasp of the ordinary reader. One of the most recent and most complete of these books of reference is that published under the title of "The Insane and the Law,"[1] which will be found to be a most useful guide as to the detention, treatment, and other matters connected with the civil and criminal relationships of the insane. We may add in conclusion that an interesting discussion followed the reading by Dr. L. WEATHERLY of a paper on the Law in relation to Single Patients at the recent meeting of the British Medical Association.

[1] The Insane and the Law. By Percy Smith, M.D., F. Pitt-Lewis, Q.C., and A. J. Hawke. J. & A. Churchill. London: 1895.

PRESENTATION.—Mr. W. J. C. Keats, L.R.C.P. Lond., M.R.C.S., on his leaving, after four years' service, the female side of the Greenwich Union Infirmary and the Workhouse, to take the medical superintendence of the male side, has been presented by the sisters and nurses of the Infirmary with a dressing table set in silver and tortoiseshell, and by the nurses of the Workhouse with a handsome brass inkstand, as marks of their esteem.

Annotations.

"Ne quid nimis."

FIELD-MARSHAL LORD WOLSELEY AND THE ARMY MEDICAL STAFF.

WE are informed that at one of the last parades held by Field-Marshal Lord Wolseley in Dublin, observing that the men of the Medical Staff Corps attending the parade saluted on his arrival on the ground by "carrying swords," he immediately directed Major-General Montmorency (Viscount Frankfort de Montmorency) to bid the medical officer commanding to issue the order "return swords," and that when giving General Montmorency these instructions Lord Wolseley added that "these men have no right to draw their swords; they are not soldiers, but civil attendants on the sick." It is well known in Dublin military circles that the medical officer in command on the occasion has reported the circumstances of the case and requested written instructions as to whether in future, if such an order be again issued, he is to obey the General Officer Commanding or the Queen's Regulations, under the directions of which he was very properly acting at the parade. We do not doubt the nature of the answer which he will receive, but may be permitted to dwell a little upon the slight—for such it may be regarded—that the Commander-in-Chief-elect has put upon a branch of the service. Lord Wolseley is a most distinguished soldier, and the post to which he is to be called is one imperatively demanding wisdom and justice, and that his reputation for these qualities should be universally recognised. It is to these qualities we appeal when we ask him to reflect that the officers and men of the Medical Department of the Army have to endure the same perils and hardships which he, in common with the distinctly combatant branches, has endured. He must, we feel, certainly know how important well-directed medical aid is on the field of battle in these days of arms of precision, how great the necessity is to increase that feeling of *bonne camaraderie* which must exist between the different departments of an efficient army, and of what consequence it is to the welfare of our troops to procure the services of medical officers, not only competent in their art, but able, by general education and knowledge of the world, to fill efficiently the position of an officer in the army. It will be altogether impossible to obtain such men for the Army Medical Staff if the term "soldier" in its fullest sense does not include those representatives of medicine who risk their lives in their country's service as freely and as bravely as the officers of any other branch of the Service. The roll of the Victoria Cross bears eloquent testimony to this fact.

THE MIDWIVES QUESTION.

TWO cases have recently been reported which show the extraordinary carelessness and ignorance which occasionally prevail among the poor with regard to the great questions of life and death. In the one a woman aged thirty-two was taken in labour at 1 A.M. and gave birth to a stillborn child. At 1.30 A.M. a female friend came in, and at about 2 A.M. a midwife. "Nothing was done by either to alleviate the suffering of the woman and there was some delay in sending for a medical man." The medical man who gave evidence stated that he was called at about 5 A.M. and found the woman much collapsed from loss of blood; two hours later she died. At the inquest a verdict of death from natural causes accelerated by want of proper medical aid was returned, which verdict seems to us to be faulty. Post-partum hæmorrhage is decidedly unnatural. But let that pass; the point on which we wish to lay stress is the

Digitized by Google

extraordinary indifference shown by the two women. There they sat for some three hours and did nothing, while the unfortunate woman's life was slowly ebbing away, and be it noted one of the women was a so-called midwife. In the other case the deceased was a child aged five weeks. A medical man had attended her, and told the parents to send for some medicine; this they neglected to do. The child died, and the parents thereupon asked the medical man for a certificate, which he very properly refused. Hence an inquest. The midwife admitted in this case that she had advised the mother to send for a clergyman to baptise the child before sending for medical aid. Further inquiries elicited the fact that the mother of the child was entitled to receive a sum of money upon the death of a baptised child, so that apparently pecuniary and not theological scruples were at the bottom of the midwife's directions, and certainly clubs founded on this basis seem to us to furnish a stronger argument against infant baptism than any Anabaptist ones. Anyway, cases like this would appear to strengthen the hands of those who object to infant insurance. The verdict in this case was the same as in the former, although given by a different jury. Neglect is common enough, but that it is natural we certainly doubt. One juryman remarked that all midwives ought to be certificated. Be this as it may, indifference such as is shown in the two instances on which we have commented is happily not common in any rank of life.

THE PROFESSOR, THE MAGISTRATE, AND THE LAW.

PROFESSOR RAY LANKESTER is a man of respectability and personal honour as distinguished as his learning; Mr. Newton is an upright judge; Constable Wise, 11 C R., and Constable Hutchins, 29 C R., are unimpeachable witnesses; and Inspector John Cox is another. We—at least, we hope it—are fair-minded. Having thus cleared the ground, we desire to comment briefly on the awkward dilemma which has brought these individuals, in themselves unexceptionable, into relations whose asperity has been so clear and unavoidable, and whose results must be to one—the one who went to the wall—as annoying as the mind can well imagine. Some of the facts in the dispute which recently took place between Professor Ray Lankester and certain of the C Division of Police are not denied. Professor Ray Lankester was standing still at a time when and in a place whence he was told to move on. He did not move on. Thereupon he was arrested. He says that he did not understand that he was being ordered about by the police, being a new hand in a fraças with the force, and that he waited to get a cab to come to him at the kerb. The police say that he refused to move in a disorderly manner, and incited six or eight other characters, professionally disorderly, to do the same. On being arrested Professor Ray Lankester, remembering who he was and what he had at stake, described the proceedings of the police as silly. The police hold that he confessed in those words to personal silliness, which is different and not borne out at all by the subsequent attitude of the arrested man. Before Mr. Newton the insinuation was made that Professor Ray Lankester was drunk. The case was adjourned for a week, during which time Mr. Newton suffered a good deal as he pondered it in its different bearings. Upon the resumption of the hearing Professor Ray Lankester proved by several witnesses that he was not drunk at the time, and could not have been, so the insinuation was withdrawn, and the magistrate was very severe with the prisoner's attorney for disproving it, forgetfully alleging that it had never been made save by that same attorney! Then Professor Ray Lankester told his story, to the truth of which he had no witnesses, the six or eight disorderly characters having been let go free by a gallant constabulary. The magistrate heard Constable Wise's story again, and Constable Hutchins's confirmation thereof, and gave judgment in accordance with their version of the story. "For," said Mr. Newton, "I have known the officers ever since I have been sitting at this court, and I have never heard their truthfulness questioned." So Professor Ray Lankester was bound over to keep the peace in the sum of £10, though, as he pointed out, his record was better than the constables', for he had been a respectable, sober, and honourable man in the eyes of other men for over thirty years, whereas the admirable *dossier* of the policemen only claimed to extend over twenty years. We tender our sympathies to Professor Ray Lankester, who, though not a member of our profession, is closely connected with medical work both by family ties and the nature of his well-known occupations.

ANALYSTS AND MILK ADULTERATION.

IT is a pity that something cannot be done to put an end to the farcical proceedings which occur over and over again in the police-courts in connexion with summonses for milk adulteration. It is wearisome to read almost every week that the public analyst certified to the effect that the milk was adulterated with a percentage—in cases of dispute generally small—of water, but that the officials at Somerset House, on the matter being referred to them, reported there was "no evidence of the presence of added water." The case is then usually dismissed, the authorities who undertook the prosecution having to pay the fee for the Somerset House certificate and the costs of the court. Such a case occurred last week, when Mr. Bevan, the analyst to the Middlesex County Council, certified of a certain milk that it contained 8 per cent. of added water. This analysis was confirmed by Dr. Stevenson and Mr. Hehner. The referees at Somerset House, however, could not regard the milk as adulterated. The summons was dismissed. These differences of opinion arose most probably from different views as to the standard normal quality of milk. Somerset House officials maintain one standard and public analysts another, and so long as this state of things continues so long will it be a farce and an incongruity to institute proceedings, or at least whilst there is a possibility of the results showing upon the standard of the public analyst that the milk is adulterated, and upon the standard of Somerset House that it is genuine but of poor quality. We assume that in these cases the analytical results are in agreement, and it is only their interpretation which gives rise to these differences of opinion. That the question is beset with some difficulty we are aware, but surely the public analysts and the Somerset House officials, being members of one profession, could meet together and discuss this subject quietly and in a purely scientific spirit, with the view of smoothing down the contentions which lead them to disagree, and which can only bring ridicule and contempt upon themselves and their work from a public ignorant of the real causes of the differences. The public analysts are, of course, in a large majority, and their opinions are entitled to be heard; and their action, contrary to that of Somerset House, has a tendency to raise and maintain the quality of our milk-supply rather than to countenance the selling of milk of a most enfeebled description. Somerset House officials argue that, when it is found that a cow yields milk of a very low quality, in the interests of justice they feel bound to adjudge all other samples by this genuine but poor and abnormal specimen. In taking this view, however, it is obvious that the lowering of the quality of our milk-supply is encouraged—that is to say, there would be nothing to prevent the watering down of a rich milk to this low standard, and in some

Digitized by Google

cases the addition of water for this purpose might be considerable. Worse than that, the bulk of the milk might be increased, for aught that is known to the contrary, with a veritable solution of filthiness abounding in disease. We repeat that we trust that the analysts and Somerset House officials will be led to unite on this question, and will arrive at some amicable arrangement which shall be just to the public and to the seller, and bring no longer any discredit upon themselves and their profession, as in the ridiculous and unedifying spectacle which they present in those cases in which the "summons is dismissed" because one analyst says that the milk is adulterated and another that it is not. If this cannot be done, then we appeal strongly to the Food Products Adulteration Committee, whose labours will recommence next session, to suggest a way out of this absurd and grotesque position.

A CASE OF SYMPHYSIOTOMY.

THE current number of the *Revue Obstétricale Internationale* contains an interesting report on a case of symphysiotomy occurring in Professor Crouzat's clinique at Toulouse. The indications for the operation were those which we ourselves regard as the most important for undertaking the operation—namely, failure of the forceps to effect delivery, an absence of any great pelvic contraction, and the fact of the child being alive. In the case referred to, Tarnier's forceps was twice used, but the fœtal head could not be made to engage in the pelvis. Symphysiotomy was then performed by Professor Jeannel. The operation appears to have been an easy one, except for a little preliminary difficulty in arresting the hæmorrhage. The pubic bones were separated for six centimetres and a half. The child was then easily delivered with Tarnier's forceps. The patient made a good recovery, getting up thirty-five days after the operation. The event as regards the child, however, was unfavourable. It seems that somewhat extensive bruising of the head was caused during the attempts to effect delivery with the forceps. These injuries, in place of rapidly improving and disappearing within a short period after birth, as is generally the case, became the starting-point of a suppurative cellulitis, which proved fatal in fourteen days. The lesson of the case would seem to be that the unfavourable result to the child might have been avoided if the attempt to deliver with the forceps had been less vigorous, and if symphysiotomy had been resorted to earlier.

LONDON'S FUTURE WATER-SUPPLY.

AFTER all, Londoners may have reason to be thankful that they were within measurable distance of a water famine last summer and last winter, since it has brought the water question into extraordinary prominence, amounting to an enthusiasm which may perhaps cause our legislators to look elsewhere and seek a supply about the abundance and quality of which there shall not be the slightest doubt. The Welsh project is the one most favourably considered, and it is even urged that if London is apathetic much longer in the matter of securing a new water area there will be few watersheds left, as those which exist now are being rapidly secured and appropriated by provincial districts. A committee of the London County Council have already inspected the area involved in the scheme of Mr. Binnie, the County Council's engineer, to bring a supply of water to the metropolis from Wales. Their report was presented at a meeting of the Council last Tuesday. The committee were very much impressed with the scheme of reservoirs which appear to possess all the advantages of a pure and plentiful supply. On the former point, that of purity, the chemist has already reported, but it will be more satisfactory to have further information than that now possessed by the Council, and samples of the water for analysis will shortly be submitted, not only to the Council's chemist, but also to an independent chemist to be hereafter selected. With a view to proceeding as rapidly as possible with the surveys of the Usk and Llangorse areas, and completing the survey of the Upper Wye Valley, the committee, acting under the authority conferred by the Council's resolution of July 30th authorised the engineer to retain the services of Mr. R. Allen and Mr. Stillingfleet at salaries at the rate of £200 a year each, and to negotiate with Mr. Hassard, whose name has been for some years associated with a scheme of supply from Wales, for all his plans and sections derived from the information of the Ordnance sheets, especially those relating to Llangorse and the Upper Usk and part of the conduit to London. The assistants above mentioned are at work contouring the various reservoir sites and setting out the necessary railway diversions, and they have commenced with the catchwater conduits in the Usk Valley. It is pointed out that one of the advantages of the scheme is that it may be carried out by instalments, and that, assuming the present sources of supply to be maintained, a supplementary supply of purer and more wholesome water may be obtained from Wales sufficient for the requirements of London for forty years hence, at a cost little if at all exceeding that which would be incurred by the formation of reservoirs in the Thames Valley. At the same meeting of the Council on Tuesday last the Parliamentary Committee submitted a report stating that as eight Bills for the purchase of the water companys' undertakings had been suspended they had had to consider what course should be taken in regard to them. In the end they recommended that the Council "do invite Her Majesty's Government either to deal with the question themselves or to appoint a Royal Commission to do so." Mr. Stuart, M.P., moved as an amendment "That the Bills for the purchase of the London water companies be proceeded with." This amendment, however, was lost by a majority of one, the numbers being 54 against it and 53 in its favour. The London Water Bills are therefore abandoned for a time.

COGNAC v. CORN SPIRIT.

AT a recent meeting of the Académie de Médecine M. Daremberg endeavoured to prove that while both beverages are hurtful, if not poisonous, the higher-priced cognac brandies are relatively much less wholesome than (as one commentator puts it) the *eaux-de-vie* that are sold for two *sous* over "the zinc"—that is, retailed in the low drinking-establishments which are just as common in Paris as gin palaces are in London. Chemical analysis shows that what are generally esteemed as the best brands contain a far larger proportion of furfurol and amylic alcohol than do the cheaper spirits distilled from corn, and for this reason alone, even though there were no other, the use of cognac must be injurious to health. M. Daremberg, however, does not rely solely upon chemistry in support of his theory, but maintains that his thesis is sustained and confirmed by the results of his experiments on animals. Ten cubic centimetres of "authentic" cognac, costing sixty francs the bottle, when injected into a vein in a rabbit's ear caused instantaneous death, whereas a similar dose of promiscuously purchased *eau-de-vie* was not attended by immediately fatal effects. The opposition was represented chiefly by M. Laborde, who pleaded the extreme sensitiveness of rabbits to the action of alcohol, as well as the uncertainty attending intra-venous injections, which may kill the subject quite irrespectively of the nature of the fluid introduced. The speaker had, moreover, analysed cognac himself, and found it to contain little or no furfurol. In his opinion the alcohol of commerce must necessarily be more injurious than that derived solely from the grape. M. Magnan agreed with the originator of the discussion that all alcohols were poisons. He, too, had performed

Digitized by Google

some experiments, but the subjects operated upon were dogs. Fifty grammes of wine alcohol caused depression and drunkenness, which disappeared in about five hours. Alcohol made from beetroot produced a comatose slumber with complete anæsthesia after from eight to ten minutes, this condition lasting twenty-four hours and the animal continuing out of sorts for several days. Alcohol extracted from maize gave similar results, with the addition during the coma stage of subsultus tendinum. No alteration of the consecutive phenomena was observable on repetition of the experiments after rectification of the three alcohols. On conclusion of the discussion the Academy decided to submit the question to a commission consisting of MM. Bergeron, Laborde, Lancereaux, Riche, Motet, and Magnan. The commentator already alluded to[1] terminates his annotation with the following sensible remarks: "When the best cognac is misused it becomes worthless. What should be avoided is the habitual consumption of eau-de-vie, the *petit verre* after each repast, even though it should be 'authentic' cognac. *Petits verres* soon accumulate in the organism; the hardest stone yields to the constant drop."

ISOLATION ON A BACTERIOLOGICAL BASIS.

MR. WYNTER BLYTH has just presented a special report to the Marylebone Sanitary Committee on the desirability of providing in the district facilities for the bacteriological examination of cases notified as diphtheria. The necessity of such a course is based in the main upon the fact that several urgent cases of diphtheria—presumably from Mr. Blyth's district—have recently been refused admission into the Metropolitan Asylums Board hospitals owing to the accommodation for diphtheria cases being exhausted. Mr. Blyth points out to the sanitary committee that in all probability a considerable number of cases notified as diphtheria are not really cases of this disease, and the only method at the present time of settling the diagnosis of doubtful cases is by means of a bacteriological examination. In this connexion he refers to the efforts of the city of New York in the United States, and of the Bristol Town Council in this country. We note in passing that Mr. Blyth observes that Bristol is the only "public body" in this country which has organised a systematic bacteriological examination of reputed diphtheria cases; but we feel sure that Mr. Blyth will forgive us for pointing out that both Dr. Thresh in Essex and Mr. Fosbroke in Worcestershire have done much in this direction. However, to revert to the main issue of Mr. Blyth's report, he proposes, with the coöperation of the medical practitioners in his district, to obtain a bacteriological examination of all cases notified as diphtheria, and by this selective process he anticipates being able to discriminate between patients whom it is desirable to isolate in hospital and those who may be otherwise dealt with. For instance, in cases where the clinical symptoms are not inconsistent with commonplace sore-throat, and a bacteriological examination does not support the diagnosis of diphtheria, there is, Mr. Blyth observes, no need for isolation either at home or in hospital. When, however, the symptoms strongly support a diagnosis of diphtheria, while the bacteriological examination gives no decided evidence, such cases will be regarded and treated as diphtheria. Mr. Blyth particularly observes that the proposed examinations are not for the purpose of disputing, revising, or correcting medical certificates, but simply with a view of an economical selection of cases for isolation during pressure upon the accommodation. There can, it seems to us, be no objection to a trial of the proposed method, but at the same time we should decline to concede to a general principle that isolation in the future is to be dependent upon the result of bacteriological examination. A single examination necessitates a delay of at least twenty-four hours, and a delay such as this in a disease like diphtheria may often be fraught with most serious consequences. Even under the circumstances above set forth, bacteriological selection, based on examination of a single sample, should be supplemented by a full consideration of the environment of individual cases. It is interesting to reflect whether from the standpoint of economy in hospital beds exceptional facilities for bacteriological examination may not bring to light cases which would otherwise have passed unrecognised, and so tend to increase the number of true diphtheria cases seeking admission. Under any circumstances, Mr. Blyth's proposal, if carried into effect, cannot fail to add something to the sum total of our knowledge of diphtheria. We should add that Mr. Blyth's scheme has been unanimously adopted by the sanitary committee, and that it will be discussed at the next meeting of the sanitary authority. Doubtless at this discussion the isolation accommodation of London will come in for a fair share of attention.

[1] Dr. E. Masse of Bordeaux.

THE HABIT OF DIRT-EATING IN CHILDREN.

A VERY interesting paper on this curious habit is contributed by Dr. John Thomson to the recent number of the Edinburgh Hospital Reports. He gives some account of the habit as observed by travellers in different parts of the world and by agriculturists among unhealthy young animals, especially lambs. Dr. Thomson finds it occurs in two classes: (1) in cases of ill-health from tuberculosis &c., anæmia being almost always a prominent symptom; and (2) in healthy children, the habit being formed in infancy and disappearing spontaneously when the children are about three years old. Dr. Thomson regards the habit in this latter class as analogous to thumb-sucking, perpetual rocking to and fro, or constant rolling in bed, in which some children find delight and which they lose when they pass out of infancy. In the cachectic cases it has been thought that the habit might be started by an instinctive craving for earthy salts, such as lime and iron, but the evidence is not conclusive. The materials selected in Dr. Thomson's cases seem to have been chiefly wall-plaster and cinders. One child varied this last pastime by pushing the hearth brush into the ashes and then licking the dust off it as a great delicacy. The habit, as is well known, is very common among idiots and imbeciles, but Dr. Thomson's cases were free from mental disorder. Even in the cases where spontaneous recovery did not occur a very short period of treatment in hospital, during which the patient was denied access to his wonted luxuries, was sufficient to break the habit. Dirt-eating may, however, lead to serious consequences when the material eaten—such as the soil—contains deleterious matter. This is seen among the native Egyptians, who, observing the marvellous fertilising power of Nile mud on their fields, imagine it must be equally nutritious for men and habitually eat it, with the result of infecting themselves with the ova of anchylostoma, bilharzia, and other parasites.

THE HEALTH OF ARMY HORSES.

THERE is nothing particularly noteworthy in the Annual Statistical and General Report of the Army Veterinary Department for the year ending March 31st, 1895, which has been recently issued. As in former reports, it deals only with the Government horses and mules in this country, Egypt, and South Africa, those in India being excluded. The strength for the year was 13,192 horses, 1915 chargers, and 178 mules. The inefficiency from disease and injurie was considerably higher than in the previous year—5·36 per cent.—being 67·35 as compared with 61·99. No reason is given for this increase. The mortality was also higher, being 2·37 of the average strength, whereas in 1893 it was

Digitized by Google

2·09 per cent. Of the deaths 1·53 per cent. died and 0·84 per cent. were destroyed. The average number of days each horse was under veterinary treatment was twenty-one, the same as in the three previous years. There was a slight decrease in the cases of specific disease, though what is designated "epizootic fever" appears to have been rather prevalent, the percentage of admissions being 0·32 of the average strength of the army horses. The highly infectious malady of young horses popularly known as "strangles," which is a suppurative adenitis, was also more frequent than in the previous year; but no case of glanders was reported, this being the seventh year in which its absence from among army horses has been noted. This fact is sufficient proof that the disease can be eradicated and kept at bay, even without recourse being had to mallein. The admissions to veterinary treatment, as well as mortality, were greatest among young horses. The average age was nine years. A table is given showing the attendance at the classes in the Veterinary School at Aldershot, and also the results of the working of the Vaccine Institute at the same place. It appears that lymph for vaccinating purposes was prepared for 40,558 people during the year; and this, added to what remained on hand from the previous year, allowed material to be issued for 42,351 persons. The results obtained from the use of the lymph at home stations are reported as "excellent" and at foreign stations as "very good." The number of calves vaccinated during the year was 14, giving an average yield for 2897 persons from each calf; the greatest amount of lymph from one calf was sufficient for 3866 persons, and the smallest for 1200. The total working expenses of the Institute for the year, including cost of calves, instruments, &c., was only £72 11*s.* 9½*d.* Since the opening of the Institute in March, 1889, lymph has been prepared for 247,137 persons belonging to the British army at home and abroad at a very small cost, while regularity and certainty of issue, as well as careful preparation, were ensured. This result is highly creditable to those entrusted with the management of the establishment.

A PROPOSED SANATORIUM IN SOUTHERN ARABIA.

IN his interesting article on "The Land of Frankincense and Myrrh," in the current number of the *Nineteenth Century*, Mr. Theodore Bent suggests that the Gara Hills, situated not far from the coast of southern Arabia, would form an excellent health resort "for the inhabitants of the burnt-up centres of Arabian commerce, Aden and Muscat." These mountains are 3000 feet in height, and the ground right up to the summits is fertile and covered with grass. Clusters of sycamores give the undulating hills a park-like appearance. "Thus we wandered," he tells us, "with our strange escort for several days along the summit of the Gara Mountains, and from certain points we obtained most interesting *coups d'œil* over the whole of the frankincense country; it is just like an oasis by the sea, an undulating range of mountains, never more than 3000 feet high, separating the central desert of Nejd from the sea....To the east and west the arid barrenness of Arabia soon asserts itself, whereas the undulating Gara range, like the Cotswold, is fertile, and rounded with deep valleys running into it full of rich tropical vegetation." The travellers suffered some inconvenience from cold winds coming from the north, during the prevalence of which their native guides would not allow the camels to move. They found many pleasant wooded dells and running streams which would have been notable anywhere, but which were a marvel as occurring in sandy and barren Arabia. The neighbouring coast is almost uniformly barren and inhospitable, and there are no good harbours. "If ever this tract of country comes into the hands of a civilised nation it will be capable of great and useful development. Supposing the harbour was restored to receive ships of moderate size, the Gara Hills, rich in grass and vegetation, with an ample supply of water and regular rains, and, furthermore, with a most delicious and health-giving air, might be of inestimable value as a granary and health-resort." Aden is one of the most disagreeable and unhealthy of the dependencies of the British Crown, and the possibility of establishing a sanatorium within a few hundred miles of this important military and coaling station is worthy of consideration. Arabia is still to a large extent a *terra incognita*, the difficulties of exploration being even greater than in the case of Africa; but in these days no country is likely to remain permanently closed against the enterprising British explorer.

THE CORRELATION BETWEEN MEAT INSPECTION AND OCULAR CYSTICERCUS IN MAN.

IN the twenty-fifth *compte rendu* of his ophthalmological clinic Dr. Hirschberg gives fresh evidence of the happy influence of meat inspection on the prevalence of ocular cysticercus in mankind. It appears that from 1853 to 1866 Graefe had met with 90 cases of this affection among 80,000 patients suffering from diseases of the eye. From 1869 to 1885 Dr. Hirschberg examined the eyes of 60,000 people also affected with various eye diseases, and in 70 the cysticercus was discovered. From 1853 to 1885 this form of parasitism was met with in the proportion of 1 in every 1000 clinical cases, and in certain years (as in 1876) it was 1 in 420, 1 in 450 (in 1879), and 1 in 800 (in 1877). When the organisation of meat inspection was further perfected these proportions were considerably modified in the course of time, but not immediately. For instance, from 1883 to 1885 the cases of ocular cysticercus were still relatively numerous, but in the four following years (between 1886 and 1889) of 30,000 eye patients only one had this entozoon in the ocular cavity; and among 43,000 who came under his observation from 1890 to 1894 there were but two so affected, and they were strangers to the district. These figures demonstrate that a good system of meat inspection, in suppressing the issue of measly flesh as food for man, has at the same time almost completely abolished a rather frequent source of human ocular parasitism.

FRENCH CENTENARIANS.

OUR contemporary *Le Figaro* makes merry *more suo* regarding persons who have reached the age of 100 years, but at the same time contrives to convey a considerable amount of useful information. Until the last census, of which the results have only just been promulgated, it was impossible to determine accurately the number of patriarchs who had enjoyed the pleasures of life for a century and upwards. Once they have passed a certain limit old people get into the way of coquetting about their ages, just as though they were so many ripe dames anxious to post-date the period of their entry into the world, and until registration became firmly established a good deal of trickery in this respect used to be possible. This time, however, the exhibition of snowy locks was not looked upon as a sufficient proof of antiquity, and all aspirants to centennial honours were required to furnish substantial evidence in support of their claims. It seems that in France at the date of the census there were no fewer than 213 genuine centenarians, of whom 147 belonged to the female sex and only 66, or less than half, to the male. Thirty-three of the ladies, being celibate, were justly entitled to be called old maids, whereas the old bachelors only numbered 11. Widows and widowers accounted for 102 and 39 respectively, a discrepancy which *Le Figaro* makes use of as indicating the superior tenderness of the masculine heart, unable, like the turtle-dove, to survive

Digitized by Google

the demise of its partner. Sixteen males and 11 females were still blessed with loving spouses, but we are not told whether in any case husband and wife had both reached their century. Finally, one lady is a divorcée, and apparently attained to that condition since she became a centenarian. "Never," exclaims the writer in a paroxysm of mock-heroic virtue—"never could a man be found sufficiently hard-hearted after 100 years to endeavour to strike a balance with his bride after that fashion."

MUNICIPAL CORPORATIONS AND MEDICAL CERTIFICATES.

WE see it announced that at the meeting of the Association of Municipal Corporations, now being held in London, among other resolutions to be considered is one for the abolition or reduction of payment to medical men for certificates issued under the Infectious Disease (Notification) Act, 1889. We are curious to hear on what grounds their resolution is going to be supported. Is it that the proposer finds the Act vicious in its working, and so the certificates unnecessary? If so, he will have some rather awkward evidence against him to surmount. Or is it that he thinks medical men should work for nothing? If so, he will have to give reasons for holding that our profession should be exempt from the business conditions universally prevailing.

THE NEW ENTRIES AT THE MEDICAL SCHOOLS.

OUR statistical returns of the students who have entered upon a course of medical study at the London and provincial medical schools are not yet complete and we must hold over our analysis of the figures for a future issue of THE LANCET. Up to the present time 187 new students have entered at St. Bartholomew's Hospital, 83 at Charing-cross Hospital, 55 at St. George's Hospital, 184 at Guy's Hospital, 112 at King's College, 138 at London Hospital, 158 at St. Mary's Hospital, and 203 at University College Hospital. At the provincial schools there have been 28 new entries at University College, Bristol; 91 at Mason College, Birmingham; 59 at University College, Cardiff; 17 at Yorkshire College, Leeds; and 16 at the Sheffield Medical College. It will be seen that the list is by no means complete, and the figures when analysed later will require considerable explanation.

TYPHOID FEVER BACILLI IN DRINKING-WATER.

IT is now generally admitted that drinking-water is often the vehicle of infection in typhoid fever. The exact conditions that befriend or antagonise the specific germ in water have naturally been made the object of study by many investigators. These studies, however, have led in many cases to results so conflicting, and have been based in general on methods and material so diverse, that the chief outcome has been confusion. A paper on this subject entitled "On some Conditions affecting the Behaviour of the Typhoid Bacillus in Water" appears in the *Philadelphia Medical News* of Sept. 28th from the pen of Dr. E. O. Jordan of Chicago. The nature of the experiments is carefully given. Without going further into detail we here give the general results arrived at by Dr. Jordan. 1. The age of the typhoid fever stock influences greatly the life of the bacilli introduced into water, a freshly isolated stock possessing distinctly greater vitality than one that has been under cultivation for some months. 2. The typhoid fever bacillus, when introduced with proper precautions into sterilised Lake Michigan water, does not multiply, but may, under certain conditions, maintain its vitality for upwards of ninety-three days. 3. The colon bacillus, on the contrary, under similar conditions, undergoes rapid multiplication and may remain alive for upwards of 262 days. 4. In redistilled water the typhoid fever bacillus perishes much more speedily than in the water of the lake. 5. The quantity of organic matter (peptone) in redistilled water influences fundamentally the life of the typhoid fever bacillus, so small an increment as 0·0126 organic nitrogen (part per 100,000) causing a perceptible lengthening of life. 6. In sterilised lake water the addition of a still smaller quantity of organic nitrogen—0·0012—affects the longevity of the typhoid fever bacilli introduced.

THE ADMINISTRATION OF THE FOOD AND DRUGS ACT AT BRISTOL.

AT the last meeting of the Bristol Town Council the following resolution was moved: "That the administration of Food and Drug Acts be entrusted to the Sanitary Committee." It was stated that at present this power is in the hands of the watch committee and police, and that Bristol was the only city in the kingdom where the Act was administered by the police, but that almost invariably it was in the hands of the health committee of the Corporation. It was admitted that the police and the chief constable were in favour of the transfer. A member of the council remarked that during his connexion with the watch committee he had never heard any member ask that any single article should be examined. The objection, according to one speaker, was that the sanitary committee was a spending committee, and that it would appoint paid inspectors to carry out the working of the Act. Unfortunately the resolution was defeated, and consequently the power is still in the hands of the police. Bristol should certainly follow the example of other towns, and place this authority in the hands of the sanitary committee, as this is the most suitable body to select articles which have to be examined and analysed.

THE WEATHER AND DISEASE.

POETS and writers in all ages have made reference to the effects which changes of the weather produce in the human organism, and the archives of folk-lore would furnish much evidence that these effects have not passed unnoticed by the proletariat. Unfortunately, however, the subject has been adulterated with a great deal of superstition, which has in a great measure tended to retard intelligent inquiry. That the various atmospheric changes should have some effect upon our bodies is easily understood, for we know that alteration in the surface temperature, a change in the blood pressure or in the air pressure of the lungs, may affect the nervous system, and all these changes may be brought about by some peculiarity of the natural phenomena which we call weather. In recent years the subject has attracted attention by those most competent to deal with the matter, and lately a meteorological station has been attached to the laboratories of the Public Health Department at Rome, where lectures are given to students on the application of meteorology to hygiene. At present our knowledge of the way in which the weather acts upon the body is very limited, and must remain so until a larger number of data are collected. An attempt to trace the relation between weather and disease has recently been made by a Fellow of the Royal Meteorological Society[1] by bringing together a number of statistics dealing with the phenomena of the weather and some well-known diseases, chiefly zymotic, presenting them by a graphic method in a systematic manner. Little attempt has been made to draw conclusions from these statistics, and until they have been digested by many minds perhaps the writer was wise in his omission. There are few people who could not give instances of the influence which the weather has upon them either mentally or

[1] Weather and Disease: a Curve History of their Variations in Recent Years. By Alex. B. MacDowall, M.A., F.R. Met.S. (The Graphotone Co., London, E.C. Price 2s. 6d.)

Digitized by Google

physically, and there are many medical men (who in other directions have no opportunity for original research) who might do some useful work by recording the result of their observations on the subject, and thus add considerably to our knowledge of the *rôle* which is played by the weather in the causation or prevention of disease. On some constitutions the seasons have a marked influence. With many the spring, with its bright days and clear air, is felt to be the time of the year when they get the most enjoyment from life; while others, probably of a more sensitive temperament, experience the greatest sum of happiness and health when peaceful autumn wraps them in its serene atmosphere. On the other hand, winter or summer, as the case may be, produces in other temperaments the greatest consummation of healthy vitality. Certain changes in the weather, too, tend to increase or diminish the amount of energy that we put into our daily work, and it has been stated that in a large factory from 10 to 20 per cent. less work is done on dull days and days of threatening storm. The whole subject is one which, pursued in a proper scientific spirit, should be productive of useful results.

SOME EXPERIMENTS WITH TEA.

DR. MCKECHNIE of Talawakela, Colombo, has been making some investigations as regards the action of tea on the digestive organs. He publishes a short paper on the subject in the *Philadelphia Medical News* of July 27th. The trial experiments were carried on with test-tubes, a digestive fluid being prepared by making a glycerol extract of pepsin. The aliment employed consisted of beef fibre and egg albumen. Measured quantities of each were used, and to six test-tubes containing the meat fibre were added the glycerol extract and hydrochloric acid, and also a measured quantity of tea, different lengths of time being allowed for each infusion, varying from five to twenty minutes. A seventh tube was used to fix the time required for the digestion of the meat fibre alone, which proved to be about 110 minutes. With the tea added to the other test-tubes the time required for the digestion of an infusion of twenty minutes was the same as with one of five minutes—namely, 118·5 minutes. Another experiment was made on the same basis, but with the tannic acid precipitated by means of a gelatine solution. The result of this showed no appreciable difference in the time taken to digest that with tannic acid and that without tannic acid. The experiments were carried still further by means of a gastric fistula formed in a monkey's stomach. It was found on introducing the ingesta by the mouth that digestion was retarded about five minutes longer than when the ingesta and the tea were introduced through the mouth and the fistula respectively, thus showing that the tea exerted an inhibitory influence upon the salivary glands. When the tannic acid was precipitated and introduced in the same manner there was no difference in the time occupied in the digestion of the tea without tannic acid by the mouth as compared with that by the fistula, but there was an appreciable difference on the introduction of an infusion of twenty minutes without tannic acid as compared with an infusion of five minutes with the tannic acid removed. The peristaltic action was retarded, and the secretion of gastric juice diminished. Dr. McKechnie is of opinion that the tannic acid in the tea is not the injurious agent, but that the injury is caused by some of the less soluble extractive matters. From the results of his observations he is inclined to think that the action of tea is not so injurious as some writers think it to be. It greatly depends on the method of infusing whether its action is injurious or not. Long-infused teas seem to extract some substance, possibly an alkaloid, that has an inhibitory action on the nerves of the stomach. Dr. McKechnie also states that an infusion of tea of twenty minutes with the tannic acid precipitated has a similar bitter taste as the same tea with the tannic acid present, so that the bitterness in long-infused tea seems not to be due to the tannic acid, but to some other ingredient.

ALCOHOLIC NEURITIS IN OLD AGE.

IN the last number of *Brain* Dr. Maude publishes a brief account of a most interesting case. The patient, who was a robust country gentleman of sporting habits and used to an out-of-door life, had taken stimulants in considerable excess for at least twenty years. Even eighteen years ago no unusual daily allowance was half a gallon of beer, a bottle of sherry, and eight or ten liqueur glasses of "neat" whisky. His favourite drink was beer, and even in the summer of 1894, although over seventy-five years old, he would often consume two quarts of beer, a bottle of sherry, and half a bottle of whisky in a day. He had had no serious illnesses except broken bones from riding accidents and a fractured humerus at the age of seventy-three from a fall downstairs one evening after dinner. During the year 1894 his great muscular power became much impaired, and towards the end of the year he began to complain of severe darting pains in the left lower limb. A few weeks later the hands and feet began to swell rather suddenly, the skin became thin and glossy, while there were small ecchymoses over it. A similar condition was present on the insteps of both feet, while the calves and thighs were œdematous and the muscles shrunken. The knee-jerk could not be elicited, and the pupils were small and did not react to light. The heart sounds were somewhat feeble, but they were regular and there was no sign of dilatation. Without any previous marked change in his symptoms he died suddenly after a few minutes' dyspnœa about two months after the onset of the symptoms. Dr. Maude considers the case to have been one of peripheral neuritis, and directs attention to several interesting points, such as the advanced age of the patient, the excess of his alcoholic indulgence, and the absence of mental change; the fact also that he was essentially a beer-drinker is interesting, with reference especially to the views of the late Dr. James Ross as to the kind of alcoholic beverage most likely to produce neuritis.

LESIONS OF THE SPINAL CORD IN PERNICIOUS ANÆMIA.

A VALUABLE contribution to this subject appears in the *University Medical Magazine*, No. 7, 1895, by Dr. C. W. Burr. The study is based upon seven cases of pernicious anæmia, in addition to other cases of profound simple anæmia. Dr. Burr is of opinion that his cases prove that the coexistence of pernicious anæmia and certain lesions of the cord is not accidental. The cord was normal in only one of seven succcessive cases. The localisation of the lesion is fairly characteristic and constant. The cervical swelling is always the seat of the most marked alteration, and the lesion progressively decreases in intensity and extent at lower levels of the cord, till in the lumbar region there is either no disease at all or it is extremely slight. The only parts of the cord affected are the posterior columns, the lateral columns in or near the crossed pyramidal tracts, the direct pyramidal tracts, and (rarely) a band running forward along the circumference of the cord (direct cerebellar tracts). The grey matter is never affected seriously and rarely even slightly. The degeneration of the posterior peripheral roots, when present, is ordinarily so slight as to be of no importance. In the greater number of cases there is marked posterior degeneration with some, but much less marked, degeneration of the lateral columns in and around the crossed pyramidal tracts. The

Digitized by Google

posterior columns may be affected alone, but the lateral never alone. Almost invariably there is a band of normal white tissue separating the diseased area in the posterior columns from the grey matter. Not very rarely there are two distinct areas of degeneration in the posterior columns in the cervical region — one in the postero-internal and the other in the postero-external column, the two being separated by a band of normal or almost normal white matter. In the lower dorsal and lumbar cord the most frequent seat is midway between the posterior median longitudinal fissure or septum and the posterior grey matter. Almost always there is normal white matter between the posterior horn and the diseased area in the lateral columns. The lesion is always symmetrical in the two halves of the cord, often absolutely so, but sometimes descending further on one side than on the other.

TYPHOID FEVER AT LUTON.

THE epidemic of typhoid fever now existing at Luton does not present the town in a very satisfactory light either as regards general hygiene or hospital accommodation. The cases have, with few exceptions, occurred in the east ward of the town, and so to a large extent have fallen under the direct superintendence of one medical officer who looks after the poor of this ward. Dr. McArthur, who is in charge of this ward, does not think the epidemic is in any way due to the water-supply, as some of the houses were supplied by the water company and others were not; but he thinks in many ways that the sanitation of this part of the town is in a very bad state, and under the circumstances it is hardly possible to think otherwise. Dr. McArthur has made several statements of the defects which he considers to exist in the sanitation and has asked for an investigation to be made by some impartial person which would satisfactorily clear up the subject. With regard to the hospital accommodation for infectious diseases it proves to be absurdly inadequate. There is a building which contains *one* ward and five beds in all, and this to serve a town of something like 30,000 people! And yet over £700 have been spent on it. The authorities are at present utilising hospital tents for the patients. The inadequacy of the accommodation has before been pointed out by people competent to judge; but now that its uselessness has been proved it is to be hoped that the sanitary officers will take some steps to get it altered. The best thing that could happen would be to have the whole matter sifted by a Local Government Board inquiry and so to ascertain the bare facts of the case. We fully agree with the opinions of the local press that the matter should not in any case be treated as a "scare" and then allowed to drop; where such a number of cases occur in a small area and where accommodation is so defective there must necessarily be defects which require the fullest and most impartial examination.

THE Paris correspondent of the *Times* announces that M. Duclaux has been unanimously chosen to succeed the late M. Pasteur as Director of the Pasteur Institute, while Dr. Roux is the subdirector. These are the appointments that were generally anticipated.

IT is now understood that the alterations in the premises of the General Medical Council cannot be completed in time for the November meeting, which will probably be held elsewhere.

THE first Hunterian Society's lecture will be delivered at the London Institution by Dr. Sims Woodhead. The title of the lecture will be "The Probable Limitations of Serum Therapy."

AT the opening meeting of the Session of the Clinical Society of London (Oct. 11th) the President, Dr. Buzzard, was unfortunately prevented from being present. Consequently his inaugural address will be delivered at the second meeting, which will be held on Friday, Oct. 25th, at 20, Hanover-square.

INOCULATIONS AGAINST CHOLERA IN INDIA.

THE results obtained from the inoculations performed in India either by M. Haffkine or by others according to his method are of interest and importance in several directions. The effect of the discovery of an inoculation protective against cholera would be far-reaching enough, and might in time effect as striking a reduction of the disease in countries where it is endemic as vaccination has done in the case of small-pox in Europe. And from the scientific standpoint, if inoculations after M. Haffkine's method should prove to be thus protective against cholera, we shall have found an infectious disease where the pathogenic organism, intensified to its maximum by progressive inoculation into lower animals, can give protection to man when inoculated in minimal doses. This experience would doubtless be applicable to other diseases; and the possibilities for preventive medicine suggested by the success of the method would be all the greater now that it has been shown that divers other organisms besides the cholera vibrio when injected into experimental animals after M. Haffkine's method can produce in them an immunity against subsequent fatal doses of the cholera vibrio.

It is well known that anti-cholera inoculation has been subjected to extensive trials in India, and a summary of the results obtained during the last two years is now published by Dr. Simpson, the health officer of Calcutta, in a recent document addressed to the chairman of the Calcutta corporation. These results may be classified as—(1) the experience of epidemics of cholera that have occurred in different parts of the country among communities containing inoculated persons; (2) the general experience of Calcutta; and (3) that of certain tea gardens in Assam. As regards the first of these, undoubtedly the most important was the epidemic of October, 1894, in the East Lancashire Regiment at Lucknow. In this regiment inoculated and uninoculated appear to have been under identical conditions in all respects. Out of 133 inoculated there were 18 cases of cholera and 13 deaths, while among 640 not inoculated there were 120 cases and 79 deaths; or, in other words, the attack-rate was over 15 per cent. for inoculated and over 18 per cent. for uninoculated, a difference which, having regard to the numbers concerned, cannot be said to be of much significance. In this instance the inoculations had been performed by M. Haffkine fourteen or fifteen months previously with, it has been explained, a weaker virus than it is now customary to use. It is noteworthy, however, that the case mortality was actually larger in the inoculated than in the uninoculated class—a fact which hardly suggests that even a partial protection was here exerted. Among the troops at Cawnpore 19 cases of cholera occurred among 797 uninoculated, and none among 75 inoculated thirteen months before; but, with this exception, the Lucknow epidemic has been the only outbreak of any magnitude available to test the behaviour of cholera in the cases of those who had been inoculated some time previously. The other outbreaks recorded by Dr. Simpson are those in which inoculation has been performed after cholera has actually made its appearance. In the Manchester Regiment at Dinapore 13 cases of cholera with 9 deaths occurred. A considerable number of men were then inoculated, in all 193, and among those there were no further attacks. Among 729 remaining uninoculated there were 6 attacks with 3 deaths. At the Gya Gaol inoculations were performed during the progress of an epidemic and after 6 cases and 5 deaths had occurred. Half the prisoners were inoculated, the remainder being left

Digitized by Google

not inoculated. The incidence of the disease on the two groups was as follows:—

—	Not inoculated.		Inoculated.	
	Cases.	Deaths.	Cases.	Deaths.
During first five days after first inoculation...	7	5	5	4
During three days after second inoculation	5	3	3	1
After eight days from first inoculation	8	2	—	—
Totals	20	10	8	5

In these two instances some protection would appear to have been afforded, but it may be borne in mind that by the time the inoculations could have begun to exert a protective effect (admittedly five days or more) the disease was on the wane and was showing its decreased virulence by a diminished fatality.

A series of observations under somewhat different circumstances is recorded by Dr. Simpson for Calcutta. The number of natives inoculated in this city since 1893 has been over 4000, comprising Hindoos, Mohammedans, and a few Europeans, of all ages and both sexes. In certain houses where these inoculated people live cholera has since appeared at one or another time, and Dr. Simpson's plan has been to determine for each house so attacked the incidence on inoculated and uninoculated respectively. The disease invaded 36 houses containing between them 516 persons—181 inoculated and 335 not. Among the former 4 cases (all fatal) occurred, or 2·2 per cent.; among the latter 45 cases (with 35 deaths), or 13·4 per cent. Further, when those houses are deducted in which the inoculations had been performed less than eight days before cholera appeared we find a single attack only among 140 inoculated, while those among 265 inoculated were 39, or 14 per cent. Several noteworthy cases occur in the list. Thus: "In Rhamdone Dutt's house at Katalbagan Custee 6 persons out of 8 were inoculated in March, 1894, and fatal cholera entered the house in the following April and attacked *one of the two not inoculated*, leaving the 6 inoculated unaffected. In the house of Baboo Banikanta Mookerjee, Shibpore, 6 members of a family of 7 were inoculated in July, 1894. In March of 1895 *the only one not inoculated* was affected with cholera and died, the inoculated remaining quite well."

The test here applied is clearly less exact than that of the Lucknow outbreak, where the mode of living and the conditions of exposure may be assumed to have been fairly equal in all cases. Calcutta has been the home of sporadic cholera for generations; the opportunities of infection met with by the native population must be so many and diverse that it can hardly be assumed that in any given house affected all the inhabitants have been equally exposed to cholera infection; and, even so, other factors besides inoculation must almost certainly have been concerned with the escape of particular members of the household. Nevertheless, no great difference in exposure or susceptibility can be assumed when the totals of inoculated and uninoculated are taken, and the immunity of the former class, as far as these figures go, is sufficiently striking. One point may be commented on. If the effect of M. Haffkine's injections presents any analogy to the protection of vaccination against small-pox we should expect to find certain partly protected persons among the inoculated class in whom cholera manifests itself in a mild or modified form. The reverse has been the case, however, for of the 4 cases recorded in this class all were fatal.

In 42 inoculated cases the interval between the date of inoculation and the appearance of cholera in the house was a twelvemonth or more. One case of cholera occurred among these 42, while the 3 other inoculated persons affected were attacked, as we have seen, less than eight days after the operation. In this connexion the third series of observations recorded by Dr. Simpson may be referred to; they are the results obtained in certain tea gardens in Assam, where up to the present inoculations have been performed only with the preliminary "first vaccine" employed by M. Haffkine. Here, as in Calcutta, the incidence of sporadic cholera as it has affected inoculated and uninoculated has been observed. Collecting the cases which have occurred at one or another time in the last few months in seven of these gardens, Dr. Simpson gives us the following figures:—

Total of Uninoculated on all the Affected Gardens.[1]

			Percentage.	
In the whole population ...	5222	had 38 cases	0·73	19 deaths.
In the affected lines	374		10·16	
In the affected houses... ...	95		40·00	

Total of Inoculated on all the Affected Gardens.

			Percentage.	
In the whole population ...	2741	had 5 cases	0·18	3 deaths.
In the affected lines	369		1·36	
In the affected houses... ...	40		12·50	

It is clear that these several experiences in India, extensive as they are, have not yet been sufficient to settle the value of anti-cholera inoculation. On the one hand, the indications afforded by the Assam figures are that even the preliminary inoculations have considerable protective power, and by the Calcutta figures that the power of completed inoculation has held good for twelve months or more. On the other hand, there is the almost complete failure of any protection to the East Lancashire Regiment under circumstances better fitted for exact experiment. Clearly more facts are needed, and we are glad to see that Dr. Simpson proposes to proceed further with the arduous investigation he is now identified with. It may be assumed, we trust, that, in view of the important issues involved, the Calcutta corporation has by now sanctioned the very modest expenditure which Dr. Simpson asks for this purpose.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY meeting of the Council was held on the 10th inst., the President, Mr. Christopher Heath, being in the chair.

The best thanks of the Council were given to Mrs. Hulke for her presentation to the College of the Series of Drawings of Malignant and other Tumours collected by the late Mr. J. W. Hulke. Mr. Tweedy received a vote of thanks for his presentation to the Library of a manuscript by Archile de Verona, entitled "De Dolore Juncturarum."

The Draft Report, which is to be presented to the Fellows and Members at the meeting to be held on Nov. 7th next, was approved and adopted.

The following report from the Committee of Management was approved and adopted, viz.:—

1. That the following institutions be added to the list of recognised places of instruction in chemistry, physics, and practical chemistry and biology: (*a*) the University College of North Wales, Bangor; (*b*) Wyggeston School, Leicester; (*c*) Victoria Institute, Worcester (without biology).

2 That the National Hospital for the Paralysed and Epileptic, Queen-square, Bloomsbury, be recognised as a place of study during the fifth year of the curriculum.

Mr. Christopher Heath was reappointed a member of the Committee of Management.

A report, dated the 4th inst., from the Laboratories Committee was approved and adopted; the report was as follows:—

1. *The Work in Diphtheria for the Metropolitan Asylums Board.*—(*a*) Examination of material for diagnosis. Since June 7th 4634 specimens have been examined and reported upon. The average number of specimens examined per diem has been 45. (*b*) The preparation of antitoxin serum. Since Sept. 1st the Director has supplied about 700 doses of antitoxin serum for the treatment of diphtheria in the hospitals of the Metropolitan Asylums Board, and he hopes to be able to meet all the demands of the hospitals, which are, however, somewhat greater than was anticipated.

2. *The Goldsmiths' Company's Grant for Researches on the Antitoxin Treatment of Diphtheria, &c.*—The Committee, on the recommendation of the Director, have granted £100 from this fund to Dr. Cartwright Wood, who is carrying on investigations as to improved means of treating the horses with a view to obtaining the serum in a shorter time than is possible by the methods hitherto in use.

Mr. Howse was re-elected a member of the Laboratories Committee.

The Royal College of Physicians of London was invited to appoint six delegates to confer with a like number appointed by the Royal College of Surgeons on the question of the examinations under the five years' curriculum.

[1] Exclusive of 19 cases, with 11 deaths, in recently arrived uninoculated coolies, and 11 cases, with 5 deaths, among old uninoculated coolies regarding which returns had not been received.

CHOLERA.

THE most important item of news in regard to this disease is that which comes from Alexandria through Reuter's agency regarding a localised outbreak of cholera at Damietta. It appears that 16 cases and 9 deaths had occurred up to the 15th inst., but the disease is reported to be of mild type. The nature of the disease was, it is stated, conclusively proved by bacteriological examination. It will be remembered that it was at Damietta that cholera first appeared in the last epidemic in Egypt.

The official returns published at St. Petersburg on the 13th inst. show that for the fortnight ending Sept. 28th there occurred 4249 cases of cholera and 1701 deaths in the province of Volkymia. In the district of Berditcheff (Kieff) 57 cases and 21 deaths occurred, and in the province of Podolia 37 cases and 18 deaths. From Sept. 29th to the 5th inst. no further cases of cholera had been reported in Podolia. It may, we think, be assumed from the foregoing returns and the lateness of the season that there will soon be a still further decrease in the number of cases, and that we may hope to hear of the disappearance of the epidemic in Russia, or, at any rate, of such a reduction in the number of attacks as to render the publication of official returns no longer necessary.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6492 births and 4271 deaths were registered during the week ending Oct. 12th. The annual rate of mortality in these towns, which had been 21·0 and 19·4 per 1000 in the two preceding weeks, rose again last week to 21·0. In London the rate was 17·0 per 1000, while it averaged 23·9 in the thirty-two provincial towns. The lowest rates in these towns were 8·6 in Croydon, 13·4 in West Ham, 15·8 in Plymouth, and 16·7 in Bristol; the highest rates were 28·8 in Gateshead, 31·7 in Liverpool, 33·6 in Salford, 34·0 in Burnley, and 42·5 in Blackburn. The 4271 deaths included 895 which were referred to the principal zymotic diseases, against 920 and 871 in the two preceding weeks; of these, 533 resulted from diarrhœa, 94 from measles, 85 from diphtheria, 65 from "fever" (principally enteric), 60 from scarlet fever, 56 from whooping-cough, and 2 from small-pox. The lowest death-rates from these diseases were recorded in Plymouth, Croydon, Bristol, and Birkenhead; and the highest rates in Preston, Wolverhampton, Burnley, Salford, and Blackburn. The greatest mortality from measles occurred in Salford, Oldham, Wolverhampton, and Blackburn; from scarlet fever in Liverpool and Salford; from whooping-cough in Salford, Gateshead, and Bolton; from "fever" in Birkenhead and Sunderland; and from diarrhœa in Hull, Preston, Salford, Burnley, and Blackburn. The 85 deaths from diphtheria included 56 in London, 7 in West Ham, 6 in Birmingham, 4 in Liverpool, and 3 in Leeds. Two fatal cases of small-pox were registered in London, but not one in any other of the thirty-three large towns. There were 158 cases of small-pox under treatment in the Metropolitan Asylum Hospitals and in the Highgate Small-pox Hospital on Saturday last, the 12th inst., against 271, 234, and 198 at the end of the three preceding weeks; 9 new cases were admitted during the week, against 23, 21, and 17 in the three preceding weeks. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 2827, against 2732, 2807, and 2802 on the three preceding Saturdays; 332 new cases were admitted during the week, against 344, 339, and 252 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 173 and 158 in the two preceding weeks, rose again to 175 last week, but were 92 below the corrected average. The causes of 55, or 1·3 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Cardiff, Oldham, Bradford, and in eight other smaller towns; the largest proportions of uncertified deaths were registered in Birmingham, Halifax, and Hull.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 17·5 and 18·3 per 1000 in the two preceding weeks, rose again to 19·3 during the week ending Oct. 12th, but was 1·7 per 1000 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 14·4 in Aberdeen and 15·7 in Leith to 26·0 in Greenock and 27·9 in Dundee. The 558 deaths in these towns included 58 which were referred to diarrhœa, 11 to whooping-cough, 8 to "fever," 7 to scarlet fever, 5 to measles, 5 to diphtheria, and not one to small-pox. In all, 94 deaths resulted from these principal zymotic diseases, against 79 and 96 in the two preceding weeks. These 94 deaths were equal to an annual rate of 3·3 per 1000, which was 1·1 below the mean rate last week from the same diseases in the thirty-three large English towns. The deaths from diarrhœa, which had been 48 and 62 in the two preceding weeks, declined again to 58 last week, of which 22 occurred in Glasgow, 11 in Edinburgh, 11 in Dundee, and 8 in Greenock. The 11 fatal cases of whooping-cough showed a decline of 6 from the number in the preceding week, and included 5 in Glasgow and 4 in Dundee. The deaths referred to different forms of "fever," which had been 16, 6, and 8 in the three preceding weeks, were again 8 last week, of which 2 occurred in Glasgow, 2 in Edinburgh, and 2 in Dundee. The fatal cases of scarlet fever, which had been 5 and 4 in the two preceding weeks, rose again to 7 last week, of which 3 occurred in Glasgow and 3 in Edinburgh. The deaths from diphtheria, which had been 5 and 2 in the two preceding weeks, rose again to 5 last week, and included 2 in Dundee. The deaths referred to diseases of the respiratory organs in these towns, which had been 82 and 98 in the two preceding weeks, were 97 last week, and slightly exceeded the number in the corresponding week of last year. The causes of 27, or nearly 5 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 24·8 and 21·3 per 1000 in the two preceding weeks, rose again to 26·8 during the week ending Oct. 12th. During the thirteen weeks of last quarter the death-rate in the city averaged 23·4 per 1000, the rate during the same period being 18·6 in London and 16·5 in Edinburgh. The 180 deaths registered in Dublin during the week under notice showed an increase of 37 upon the number in the preceding week, and included 29 which were referred to the principal zymotic diseases, against 24 and 12 in the two preceding weeks; of these, 17 resulted from diarrhœa, 6 from "fever," 3 from whooping-cough, 1 from small-pox, 1 from scarlet fever, and 1 from diphtheria. These 29 deaths were equal to an annual rate of 4·3 per 1000, the zymotic death-rate during the same period being 2·8 in London and 3·4 in Edinburgh. The fatal cases of diarrhœa, which had been 13 and 8 in the two preceding weeks, rose again to 17 last week. The 6 deaths referred to different forms of "fever," exceeded the number recorded in any week since December last. The mortality from whooping-cough also showed an increase, while that from scarlet fever showed a decline from that recorded in recent weeks. The 180 deaths in Dublin last week included 43 of infants under one year of age, and 38 of persons aged upwards of sixty years; the deaths both of infants and of elderly persons considerably exceeded those returned in the preceding week. Four inquest cases and 9 deaths from violence were registered; and 55, or more than a fourth, of the deaths occurred in public institutions. The causes of 19, or more than 15 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

MOVEMENTS OF THE MEDICAL STAFF.

BRIGADE-SURGEON-LIEUTENANT-COLONEL MATURIN has arrived fom Ceylon and will be succeeded by Brigade-Surgeon-Lieutenant-Colonel Duke. Brigade-Surgeon-Lieutenant-Colonel Williams has embarked for Jamaica. Surgeon-Major Peterkin and Surgeon-Major Rhodes have embarked for India in the *Dilwara*. Surgeon-Lieutenant-Colonel Bourke has been transferred from Cork to York. Surgeon-Captain

Digitized by Google

Ritchie has arrived from Malta, and Surgeon-Captain Kennedy has arrived in that Command. Surgeon-Captain Lane has embarked for Singapore. Surgeon-Captain M. L. Hearn proceeds to Singapore for a four years' tour of duty in the Straits Settlements.

ARMY MEDICAL STAFF.

Surgeon-Major-General Robert Lewer is placed on retired pay. The under-mentioned surgeon-majors to be surgeon-lieutenant-colonels:—William M. James and Ernest H. Fenn, C.I.E. Surgeon-Captain Patrick B. Skerrett retires from the Service receiving a gratuity.

INDIA AND THE INDIAN MEDICAL SERVICES.

Surgeon-Lieutenant-Colonel F. C. Barker is appointed to be Presidency Marine Surgeon, Second District, Bombay. Surgeon-Lieutenant-Colonel J. McCloghry to be Medical Officer to the Kathiawar Political Agency and in Charge of the West Hospital, Rajkete. Brigade-Surgeon-Lieutenant-Colonel H. T. Brown, A.M.S., to officiate on the Administrative Medical Staff of the Army, with the temporary rank of Surgeon-Colonel, vice Surgeon-Colonel T. Maunsell, Principal Medical Officer, Rawalpindi District, appointed Principal Medical Officer, Chitral Relief Force. The following transfers of officers of the Army Medical Staff serving in the Bombay Command are ordered:—Brigade-Surgeon-Lieutenant-Colonel Saunderson from Quetta to Mhow District; Surgeon-Major MacNeece from Deesa District to Poona District; Surgeon-Major Gogging from Mhow District to Deesa District; Surgeon-Major Parker from Deesa District to Aden District; Surgeon-Major Banes from Poona District to Aden District; and Surgeon-Captain Parry from Poona District to Bombay District. Surgeon-Lieutenant Kilkelly is transferred from the Nagpore to the Poona District, and is appointed to the Officiating Medical Charge of the 28th Bombay Infantry. Brigade-Surgeon-Lieutenant-Colonel S. O'Brien Banks is promoted to Surgeon-Colonel in the Bombay Service.

NAVAL MEDICAL SERVICE.

Surgeon George T. Collingwood has been appointed to the *Pembroke*.

VOLUNTEER CORPS.

Artillery: 1st North Riding of Yorkshire (Western Division, Royal Artillery): Surgeon-Major T. R. Pearson, M.D., to be Surgeon-Lieutenant-Colonel. *Royal Engineers:* 1st Cheshire: Captain J. F. Blake-Campbell is appointed Surgeon-Lieutenant. *Rifle:* 2nd (Berwickshire) Volunteer Battalion the King's Own Scottish Borderers: Surgeon-Captain J. Denholm, M.B., resigns his commission; also is permitted to retain his rank, and to continue to wear the uniform of the Battalion on his retirement.

THE MADAGASCAR EXPEDITION.

The intelligence of the capture of the capital of Madagascar by General Duchesne's force, although incorrect as to the date and in other particulars, has since been officially corroborated, and the French Government is to be congratulated on the fact. Notwithstanding that there may have been mistakes in the campaign, and that the arrangements generally—and the sanitary arrangements in particular—were very far from perfect, the expedition was confessedly a very difficult one, and the operations are most creditable to the pluck and perseverance of the French army and the ability of its general. The history of the expedition, when it comes to be written, will be an interesting and instructive one. It is probable that a comparatively small force will now be kept in the country and at Antananarivo. We are glad to learn that active measures are being taken in France to secure the comfort and well-being of the invalid soldiers on their way home by giving a larger amount of accommodation to the sick and convalescents on board the transports, with plenty of fresh and wholesome food. The hospitals and sanatoria in Algiers are prepared for the reception of invalids. Telegraphic intelligence from Port Said reports the arrival there of the French troopship *Canton* on the 12th inst. with a number of sick troops from Madagascar. Over fifty men are reported to have succumbed during the voyage to Suez, and some have since died and been buried at Ismalia. The French Madagascan expedition will, we suspect, prove to have caused a very considerable expenditure of life and money.

THE CHITRAL DISPATCHES.

A telegram from Simla gives a nominal list of the officers mentioned in General Sir R. Low's dispatches for services in connexion with his force. We are glad to notice the names of several medical officers. Surgeon-Lieutenant Sutherland's services are mentioned for the action at Panjkova on April 13th; Surgeon-Colonel T. Maunsell, Surgeon-Colonel Thomson, Surgeon-Lieutenant-Colonels Donovan, O'Connor, and Simmons, and Surgeon-Major Coutts are also mentioned in the General's dispatches, and we congratulate these officers and the medical services on the part they took in the late expedition. The total casualties in General Low's column in the several actions in April last were: 2 officers killed and 13 wounded, 19 non-commissioned officers and men killed and 88 wounded, and 5 followers killed; total, 127.

DEATHS IN THE SERVICES.

Deputy-Surgeon-General R. W. Cockerill (retired) on Oct. 8th. He served in the Crimea, and was present at Inkermann and at Sebastopol, where he was wounded (Crimean and Turkish medals). He served through the China campaign of 1857–59, receiving the Chinese medal for his services. In 1869 he was appointed to a professorship in the Madras General Hospital and Medical College. He retired in 1885.

Deputy-Inspector-General J. C. Messer (retired), R.N., on Oct. 9th, at his residence in Edinburgh. He was appointed surgeon in 1852, staff-surgeon in 1861, and fleet-surgeon in 1874. He served in the Baltic Expeditions of 1854-55 (Baltic medal) and retired in 1885.

THE ARMY MEDICAL SERVICE.

The *Pall Mall Gazette* of the 15th inst., under the head of "Service Notes," contains a very trenchant paragraph as to the contemplated reform and reorganisation of the Army Medical Department, which, it says, rumour has it, will be inaugurated under the new Commander-in-Chief. Our contemporary, while disclaiming all intention of reflecting "on the courage, skill, and devotion of our army doctors, of whom, as a whole, we may well be proud," goes on to add that the department is run from top to bottom on a muddle-headed want of system which calls for inquiry and remedy.

THE FRENCH MILITARY MEDICAL SERVICE.

A number of military surgeons were nominated in a recent gazette as commanders, officers, and knights of the Legion of Honour. It is announced that the autonomy given to the medical corps is about to be revised, and that an attempt will be made to modify or cancel the powers vested in medical officers by the law of March, 1882. But this, it is to be remarked, is only a rumour, to which we have already referred.

Correspondence.

"Audi alteram partem."

ELEMENTARY EXAMINATIONS IN ANATOMY.

To the Editors of THE LANCET.

SIRS,—Is the elementary examination in anatomy as at present conducted by the Royal College of Surgeons of England a desirable one? This is a question which is best answered by a study of the requirements of that examination. The student who presents himself for this examination is required to show a knowledge of osteology and to have spent six months in acquiring that knowledge. He is not required to know anything of the soft parts, nor is he supposed necessarily to have done any dissection; at all events, he is not required to present any certificate to the effect that he has dissected. He is, in short, required to have a knowledge of the bones of the body, and he is allowed six months to acquire that knowledge. Now what is the effect of this on the average student? He knows that any student of reasonable intelligence can get up the work for this examination in three months. His teacher is able by lecturing, say, three times a week to get over the ground covered by osteology in three months—by Christmas in a winter session—after which he perhaps lectures on the ligaments and muscles of the body and any other systems that time allows him. The student faithfully takes notes of the lectures on osteology, but does he trouble to read them? No. As he knows that anyone with any intelligence at all can acquire enough knowledge in three months to satisfy the

Digitized by Google

examiners in this examination he leaves his reading for the latter three months of the winter session. He goes on attending the lectures on ligaments and muscles, &c. if he is compelled to do so, or until he thinks he has attended often enough to be "signed up," and then he disappears. He may, of course, attend regularly to the end; but in either case his mind and energies are directed towards "getting up" the work for the First Examination, and the lectures are absolutely wasted on him. He does not trouble himself about ligaments and muscles—"they are not wanted." The consequence is he spends six months in learning what he could learn in three. But this is not the worst of it; for all this time he has either not dissected or if he have he has not troubled to learn anything about his dissections because "it is not required." It is all very well to tell him that he will require a knowledge of the soft parts in his Second Examination, and that he will require a certificate to the effect that he has dissected for twelve months prior to that examination. "Sufficient unto the day ....." is his motto. He goes up for his "elementary" and passes it, and now is confronted with the "Second." He may not be able to dissect in the coming summer session, or, if able, counter attractions prove too strong for him, and he leaves his work till the next winter. He now finds he has twelve months' work to squeeze into a six months' session, and he soon realises the impossibility of it and in the end "funks" his examination. This funking in very many cases is the beginning of the end. When done for the first time it arouses some repentant feelings, but by repetition its terrors are lost and the erstwhile average student become the full-blown "chronic" who, after haunting the place for several years, either turns over a new leaf or gives up medicine altogether, either voluntarily or because he is compelled to by his friends or his teachers—in any event, after he has wasted many valuable years of his life. Of course, he is to blame, but not entirely. He at first got up the work prescribed and passed the examination, but he stopped there; to him a bird in the hand was worth two in the bush. Having passed this examination, he found it of little help to him towards the "Second." He knows nothing beyond the bones and the attachments of muscles to them. He may never have seen the muscles themselves, but has crammed up the areas occupied by their attachments from plates. Instead of his work being now in considerable part a revisal, it is all new to him. The elementary examination is a snare, and in its present form is superfluous.

Can it be remedied in any way? I think so. There is an examination which resembles it in being an elementary one and in being held by a Conjoint Board. I allude to the First Examination of the Scottish Conjoint Board. In this examination a student is required to show a knowledge of the bones and ligaments of the body and the soft parts of both extremities. Having passed this examination the student is a long way on to his "Second," at all events much of his work is revisal, and revisal is always easier than the acquiring of new knowledge. Much as we in England are in the habit of sneering at this examination it is, nevertheless, infinitely better calculated to benefit the student, to satisfy the teacher, than is the miserable fiasco called an examination which is so often held in England.

In this letter I have confined my remarks to the elementary examination; if I am permitted I shall in the near future have some remarks to make on the Second Examination.

I am, Sirs, yours truly,
EDWARD FAWCETT,
Professor of Anatomy, University College, Bristol.

THE PRESENCE OF THE DIPHTHERIA BACILLUS ON HEALTHY SURFACES.

To the Editors of THE LANCET.

SIRS,—A boy fourteen years of age had diphtheria when at school early in June—that is to say, four months ago. He was brought to me on Oct. 14th, and I sent a specimen of mucus from his throat to be examined at the British Institute of Preventive Medicine; this I did, using a perfectly new camel's-hair throat brush for the purpose. From the society's report I learn that the diphtheria bacillus has been isolated from the specimen. The boy is apparently in perfect health, and his throat to the naked eye appears perfectly normal. I am informed that the throat had been thoroughly brushed with glycerinum acidi carbolici and with sulphurous acid up to three weeks ago.

I am, Sirs, yours truly,
J. W. ASTLEY COOPER, L.R.C.S., L.R.C.P., &c.
Lower Sherringham, Norfolk, Oct. 14th, 1895.

To the Editors of THE LANCET.

SIRS,—Mr. John Terry's communication on "Sore-throats in Influenza" which appeared in THE LANCET of Oct. 12th contains many points of interest and exhibits much praiseworthy and industrious investigation. I venture, however, to think that most medical men will agree with me that the "enlargement of the papillæ," the "deep-red colour," and the "strawberry tongue" may be found in many vascular conditions of the mucous membrane of the mouth—e.g., stomatitis, follicular tonsillitis &c.—and quite apart from influenza. Then again the membrane of which he speaks is certainly, in my experience (and I have seen a good deal of influenza), no common accompaniment of that complaint, and is, I would suggest, of a distinctly diphtheritic type, due possibly to some local cause. I quite agree with Mr. Terry that the ulcerated and congested condition of the throat so often present in influenza affords a highly suitable soil for the growth and development of the diphtheritic membrane, and for its frequently accompanying bacillus, but the last word as to the *rôle* played by the Pfeiffer-Kitasato bacillus has not yet been uttered, and those who rely exclusively on microscopic tests rather than on clinical observation simply court disaster. There is no question that the diphtheria bacillus has often been found on perfectly healthy mucous membrane and has often been absent, or at any rate undetected, in many cases of unmistakable diphtheria. I unhesitatingly endorse all that Mr. Terry has said as to the misleading results of bacteriological examination of suspicious false membrane, though I can hardly coincide with his opinion that it "has nothing in common with diphtheria." For my own part, I now always look askance at every case of low type inflammation of the throat or tonsils as containing the possibilities of diphtheria, and I have repeatedly watched the gradual evolution of apparently simple catarrhal tonsillitis into malignant diphtheria, followed by paralysis or death. I have often, especially in schools, watched with painful interest this gradual evolution from simple to malignant sore-throats, where each successive case has afforded the required soil for gradually maturing the poison until it reaches its fullest virulence as undoubted diphtheria. As to the occasional symptoms of influenza, they are so numerous and protean as almost to defy enumeration, depending as they do on the particular tract on which the virus expends its force, whether that be the mucous membrane of the throat, nose, bronchial passages, lungs, or bowels; but for the purpose of diagnosis certain symptoms may be relied on as never absent—viz., sudden attack, severe nervous prostration, pain, usually severe, in the head and limbs, and copious perspiration. It is by these never-failing symptoms one should be guided rather than by the variable appearance of the tongue. I may mention, in passing, that the last epidemic has been specially prolific in cases of faucial inflammation and ulceration, often mistaken for tonsillitis. There is a growing tendency, which cannot be too carefully guarded against, to allow bacteriological examination to usurp the place of careful clinical observation and study of symptoms. It should be remembered that bacteriology is the handmaiden, not the mistress, of medicine.

I am, Sirs, yours faithfully,
CHAS. EGERTON FITZ-GERALD, M.D.St.And.
Folkestone, Oct. 14th, 1895.

SPASMUS NUTANS AND HELMINTHIASIS.

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Oct. 5th Dr. George Dickson, describing a case of spasmus nutans which occurred in his practice at Edinburgh, gave a full account of the ordinary features of this complaint and made the following remark: "Dentition must be looked upon as by far the commonest existing cause, but it is probable that any other reflex irritation would—other things being equal—produce the same effect." Will you allow me to inform Dr. Dickson and the other readers of THE LANCET that I have lately seen a case of spasmus nutans which was coincident with tænia nana,

Digitized by Google

and which I have reason to refer to this intestinal helminthiasis? The full account of the case is given in the *Bullettino 3° della Società Medica Pisana*. But it is well to bear in mind that only microscopical examination of the fæces can establish such coincidence of tænia nana with spasmus nutans or other disorders. I take, also, this opportunity of stating that I have recently examined a tænia which was passed by a child in the neighbourhood of Pisa, and which presents the characteristics of tænia flavopunctata (Weinland), of which till now only four examples occurring in man were known. I will give very soon a full account of it, but I wish to remark here that the eggs of tænia flavopunctata differ from those of tænia nana in being larger (being about 75 millimetres in diameter, whilst those of tænia nana rarely reach 50 millimetres in length), and that whilst the eggs of tænia flavopunctata have a striated outer shell, those of tænia nana possess an unstriated shell. The two large tæniæ of man (tænia solium and tænia mediocanellata) possess each a striated shell, but this striated shell is not the very outer shell of the same egg; the embryonic shell which is seen free in the fæces, being deprived of the outer shell of the egg, but having a diameter of no more than between 33 and 36 millimetres, cannot be confounded with the larger egg of tænia flavopunctata.

I am, Sirs, very truly yours,

Via San Lorenzo, Pisa, Oct. 9th, 1895. P. SONSINO.

"THE BATTLE OF THE CLUBS."

To the Editors of THE LANCET.

SIRS,—May I remind your readers that the profession in this district have been fighting the medical aid question since August, 1893, when the following resolution was unanimously adopted at a meeting held in my house? A copy was published in THE LANCET with appended signatures. The resolution was as follows: "That in consequence of the abuses brought to light by the inquiry into medical aid associations by the General Medical Council we have decided that we cannot in any way countenance these bodies, and we therefore refuse to recognise their medical officers professionally, in consultation or otherwise, until such abuses are removed." It was further resolved to endeavour to secure the coöperation of the profession in neighbouring towns and to get the matter brought before the British Medical Association meeting with a view to the expulsion of these men. This was entrusted to Dr. Leslie Phillips of the Medical Defence Union. It was also resolved to secure the coöperation of dentists, druggists, instrument makers, and medical agents. The local dentists gave us their support, as did a considerable number of medical agents. It was distinctly understood that no patient should suffer for want of attention as any of us would assume the charge of medical aid association patients, and, if necessary, give them gratuitous attention. That local combination can do much to hinder such abuses there can be no doubt, and I rejoice to see that other localities are following in our wake, but I venture to think that the time has arrived when something more general is necessary. To instance this locality, when those of us who were constantly called in consultation refused there was no lack of material from neighbouring places, and the larger the places and the more prominent the consultant the more ready he appears to be to join these men in their cases, and often to inconvenience himself to aid them in their difficulties. The height of absurdity seemed to be reached when one of the medical aid association officers was summoned for an error in the diagnosis of a case of small-pox; although he appealed to me most urgently to give evidence on his behalf I resolutely refused; but he was defended by the Medical Defence Union and a prominent consultant—a personal friend of my own—from a large town in the district was present to give evidence upon his behalf. Of course I felt obliged to resign my membership in the Medical Defence Union and to avoid meeting my friend in future, as it was generally understood that such consultants should be eschewed. I fear it will be only by such means that they will be forced to take action, but the body of the profession have it in their power thus to force them to assist in a necessary reform to remove an evil whose gigantic abuses should have roused them to vie with each other as to who should be the pioneer in such a movement.

To my mind there is no doubt that medical aid associations will ere long cease to exist, and if they have been the means of ascertaining who are the men in the profession willing to support them they will have been of use. I trust, too, that it will be the means of reforming the club system as a whole, for, being entirely independent of such practice myself, I can see that in many, including registered, societies similar abuses exist to a more or less extent, and it is the duty of all men holding such appointments to insist upon the removal of all these, so that medical officers of the medical aid associations cannot meet them with a *tu quoque* argument. I am thankful that the cause has such a powerful advocate as THE LANCET, and I can assure you that we in Kidderminster are determined to use every endeavour to safeguard the honour of the profession against such practice.

I am, Sirs, yours faithfully,

J. LIONEL STRETTON,
Secretary, Kidderminster Medical Society, &c.

Kidderminster, Oct. 14th, 1895.

To The Editor "THE LANCET."

DEAR SIR,—I am in receipt of Copy LANCET you sent me on Saturday last and note your article on this Society. And am much supprised at the one sided and untrue statement by your Special Correspondant. I think it would have been only Common Courtsey for him to have seen me and had his figures confirmed before rushing into print. In the first place he states we sweated our Doctors out of a profit of £231 during 1894, whereas our Balance on the year after paying salaries and expenses was only £40 (as per printed report enclosed), and out of this amount we increased our Junior Medical officers salary £25, then, again, he states the Committee get paid this is another false statement. The Committee work for nothing, and again he states he was told the medical officers had to Consult with 60 patients per hour, we I am astonished how any sane man should write down a statement of that discription, for he must know that it would be impossiable to get the patients in and out of the room in that time if he divides his figures by 8 or 10 he would be nearer the mark. With regard to stock mixtures, we do not use them. You will, therefore, see we are not such terriable sweaters as your Correspondant would try to make us out to be in his unfair statement. I must again express my supprise that a paper of such high standing as the LANCET should be a party to such a partial statement when you could of been supplied with facts for the asking.

Yours faithfully,

WM. COULSON, Secretary.

Lincoln Oddfellows' Medical Institute, 12, North Parade, Lincoln, Oct. 14th, 1895.

*** We have examined the printed report sent to us with the above, and we find in it confirmation of our Special Commissioner's statement, and contradiction of Mr. Coulson's indignant letter. The balance of the Lincoln Oddfellows' Medical Institution for the year ending Dec. 31st, 1894, was not £40 but over £200. Our Special Commissioner was informed that on *one* occasion sixty patients had to be seen in an hour, and this is perfectly credible. With regard to payments to the committee, our Special Commissioner was referring to the payments which have been made to the secretary, the sub-secretaries, the treasurer, and the auditors. He should not have alluded to these persons as the committee, but the report shows them to have received the sum that he mentions—and more. Does Mr. Coulson say seriously that a dispensary at which over 30,000 prescriptions have been made up in the course of a twelvemonth is unprovided with stock mixtures? There is no harm in stock mixtures if they are made of good ingredients and are kept in sufficient variety and are renewed with sufficient frequency.—ED. L.

"UNUSUAL PROCEDURE AT AN INQUEST."

To the Editors of THE LANCET.

SIRS,—I am a little surprised that you should have followed the lay press in the misconception that the authority possessed by the foreman of a coroner's jury exceeds in any degree that of his brother jurymen or that the legislature recognises any distinction of one juryman from another.

Digitized by Google

The statutes under which coroners' juries are called upon to serve are the Juries Acts, 1825 and 1870, and the Coroners Act, 1887, and certainly in neither of these is mention made of such a person as a foreman, and I am unaware of the recognition of such a one in any statute. There cannot, therefore, be any statutory obligations to administer the oath primarily and separately, as stated in your annotation on the matter, to a person unknown to the law. Section 3 (1) Coroners' Act, 1887, provides that the coroner shall issue his warrant for summoning not less than twelve or more than twenty-three good and lawful men to inquire as jurors touching the death, &c. And Sub-section 3 provides, "When not *less than twelve* jurors are assembled they shall be sworn by or before the coroner diligently to inquire," &c. Further, Section 4 (5) provides: "In case *twelve at least* of the jury do not agree on a verdict the coroner may adjourn the inquest to the next session of Oyer and Terminer and Gaol Delivery held for the county or place in which the inquest is held, and if after the jury have heard the charge of the judge or commissioner holding such sessions twelve of them fail to agree on a verdict, the jury may be discharged by such judge or commissioner without giving a verdict."

I think the above extracts support me in the view I have always taken, that the foreman of a jury is chosen by his fellows rather as a matter of convenience, in order that their opinions may be canvassed by him, and through him their conclusions be conveyed to the coroner. In other words, he is simply chosen as their spokesman. Under the heading "Jury," Number, Sidney Taylor, on the Law of Coroners, says: "Not less than twelve nor more than twenty-three. As a verdict cannot be given by less than twelve, it is as well to have thirteen or fourteen in all cases, and even more where there is any probability of an adjournment, so that the death or illness of one or two of the jurymen may not bring the jury under twelve." The same authority, under "Swearing," &c., says: "Not less than twelve having been assembled, a foreman should be appointed. This is generally done by the jury selecting one of their number, but the coroner will make his own appointment if the jury do not agree. The jury should then be sworn in the form provided in the schedule to the Coroners' Act, 1887. This *need not be supervisum corporis* or all at the same time. ..... Some coroners swear first the foreman and then the rest, *but nothing is gained thereby*, and it is more convenient either to swear all at once on several Testaments or to swear half first and then to swear the remainder" acording to a short form given. It is the practice of some at least of the metropolitan coroners to adopt the plan of swearing the jury all together on several Testaments, and in cases where the jury do not without undue delay select one of their number as foreman to nominate the first on the list to so act, a plan adopted in other courts and for which further support is found in "Jervis on Coroners," p. 17, as follows: "The oath should be first administered to the foreman, who may be the first juryman called or may be nominated by his fellows."

I think it reasonable to assume that the Legislature contemplated, *inter alia*, the possibility of absence of unanimity arising in coroners' juries, hence the number to serve not being limited to twelve, as is the case of other common law juries. In the particular instance out of which the question here discussed arose I pointed out to the foreman that while I regretted he was amongst the dissentients he might have been the only one to disagree, and then how manifestly unfair would it have been not only to the other members of the jury, but also to an accused person, if undue weight were to be given to the opinion of one member; and may I not reasonably add that if one member of a coroner's jury had the power to veto the conclusions arrived at by the other members, a door might thereby be opened to the perpetration of injustice and corruption in their worst forms.

I am, Sirs, yours truly,

G. E. YARROW,

Deputy Coroner for North-East London.

Duncan-terrace, N., Oct. 9th, 1895.

"ADVERTISING IN HIGH PLACES."

To the Editors of THE LANCET.

SIRS,—Has not your correspondent "M.R.C.S." overlooked your headline "Audi alteram partem"? I should have been glad of the opinion of the best authority in some urgent cases, but have been deterred from seeking the same, as in a recent case, by the almost certain fact that during August and September one's patient would no doubt see a reliable substitute, but not Dr. or Mr. ——. I cannot help thinking that a list of probable dates of absence from home of eminent physicians and surgeons in THE LANCET or other professional paper would be of service to others as well as to,

Yours faithfully,

B. FARADAY GILES, M.D. Durh.

Hornsey, N. Oct. 14th, 1895.

AN EARLY METHOD OF INTESTINAL APPROXIMATION.

To the Editors of THE LANCET.

SIRS,—A few days ago, while looking up a subject in South's "Translation of Chelins's System of Surgery," published in 1847, I found on p. 464 of vol. i. the following words: "In complete division of the intestine Denans introduces into the upper and lower end of the gut a silver or zinc ring, thrusting it in inwards about two lines from each end; he then brings the two ends together over a third ring, of which the two springs retain the external rings. The included ends of the intestines mortify, and the rings thereby becoming unfastened are discharged by stool after they have united the serous surfaces in contact. This experiment in the dog has most successful results."

Chelins gives as his reference "Recueil de la Société Royale de Médecine de Marseille, 1826." The resemblance which the above-mentioned instrument must have borne to the modern Murphy's button is, indeed, remarkable, for while its mechanical details were evidently strikingly similar its mode of action must have been precisely the same. Truly there is nothing new under the sun.

I am, Sirs, yours truly,

Birmingham, Oct. 15th, 1895. LEONARD GAMGEE.

DENTAL QUACKERY AND THE GENERAL MEDICAL COUNCIL.

To the Editors of THE LANCET.

SIRS,—As an old reader of your valuable journal, may I respectfully ask the General Medical Council if the time has now arrived for vigorous action against breaches of the memorandum issued a long time ago to registered dental practitioners with regard to the employment of unregistered persons to perform operations in dental surgery? It is notorious that with very few exceptions that memorandum has been and is now wilfully ignored. How farcical is this state of affairs, and what a greater farce is the present Dental Act. I would also like to ask if the great army of dental quacks (companies and individuals) now practising dental surgery and administering anæsthetics *ad lib.* cannot be convicted under the Medical Act. In the face of the grossest ignorance and assumption on the part of unregistered persons, it is surely time for amending the Dental and Medical Acts. I am, Sirs, your obedient servant,

Oct. 15th, 1895. INQUIRER.

"SPECIALISM IN MEDICINE."

To the Editors of THE LANCET.

SIRS,—The letter of your correspondent, Mr. Blake, in THE LANCET of the 14th ult., gives the two common objections to specialists, each of which is opposed to the other. He remarks that "any good all-round physician or surgeon" would be much preferred to a specialist, though he adduces no reason for this statement; and, a little later, "were the specialist to strictly adhere to the particular branch which he has chosen ..... he would be held in higher estimation" &c. According to the first statement the more varied (all-round) his practice the better a consultant would be, and to the latter the more limited. No doubt there is some truth in both, but the practical issue would be that a specialist should first be a good "all-round" practitioner, and then, having a predilection for some branch and giving special attention to it, he would gradually become more and more a true specialist, though it is probably advisable that even a specialist should have some general work. Every practitioner is probably at heart a specialist, and takes more interest in, and devotes more attention to, certain diseases than others. And it

Digitized by Google

would be to the interest of the profession to develop this tendency, for work done *con amore* is almost always well done. Medical science is much too large for the ordinary, or more than ordinary, individual to grasp, and one instinctively turns to those having special knowledge and experience in cases of difficulty. The general practitioner himself when ailing is one of the first to seek the aid of the specialist.

It should be, and no doubt is, a great relief to the practitioner to find his clients acknowledging the impossibility of one man being able to deal adequately with every variety of disease and recognising that limited branches can be better practised by those who give them particular attention. In the country the specialist cannot exist, but the advantage of a town (if it be an advantage) is that special ability in particular departments can be obtained. The general practitioner has a fancied grievance against the specialist in that he thinks he takes a good deal of the former's work. In these days of competition and bad trade this is a serious matter, but on consideration it will, I think, be found groundless. In the first place, if the specialist were not what he is he would be a general practitioner and compete directly for all medical work; and, secondly, cases of special difficulty or duration will probably not increase the reputation of the general practitioner, who will gain rather than lose by consulting a specialist. The patients of the general man may certainly of their own accord consult the specialist for slighter causes and oftener than the practitioner would like. But they still remain his patients, while he is saved the labour of keeping up with medical knowledge in that department. The majority of diseases must, however, be treated by the general practitioner. The consulting physician or surgeon objects to specialism with more reason, yet even in his case similar arguments apply and will probably lead to all physicians and surgeons in large cities becoming specialists more or less. Already in London many leading medical men are consulted for their special rather than their general knowledge, and no mention of names is needful to show that they are sought after for their special knowledge of nervous, heart or chest diseases, of uterine or urinary affections, and even of such limited departments as hysteria, gout, or diabetes. These physicians and surgeons have the advantage of being general in name but special in practice—i.e., private practice. Specialisms make advance possible and life endurable; they relieve the general practitioner of a troublesome class of cases, and, instead of narrowing a man's views, wider them. My own experience has been that general men treat cases conventionally, the special man on their merits.

In answer to "A General Practitioner," I neither attempt to justify dishonesty nor to deny his particular facts; what I do deny is that they are peculiar to specialists or prevalent among them, as he would lead others to infer. I have heard of quite as much dishonesty in connexion with a hospital surgeon (general) and a leading man in the profession.

I am, Sirs, yours faithfully,

Oct. 2nd, 1895. A SPECIALIST.

REGISTERED SLAUGHTER-HOUSES.

To the Editors of THE LANCET.

SIRS,—In 1877 the township of W—— was constituted a local government district and a local board was elected. Slaughter-houses then in use were registered under Section 127 of the Town Improvement Clauses Act, 1847, which Act is incorporated with the Public Health Act of 1875 (Section 169). Two of the registered slaughter-houses have proved to be in undesirable situations, even when in good order and properly kept, and when neglected become nuisances. Can the registration be revoked, or is there no other remedy than dealing with them from time to time under Section 91 of the Public Health Act of 1875?

I am, Sirs, your obedient servant,

M.O.H.

GLASGOW EASTERN MEDICAL SOCIETY, SESSION 1895-96.—The opening meeting of this society was held on the 9th inst., when the following gentlemen were appointed office-bearers for the ensuing year:—President: Wm. Patrick, M.D. Vice-President: Alex. Patterson, M.D., F.F.P.S.G. Treasurer; Thos. McMurray, M.B. Secretary: Jas. Craig, L.R.C.P. Eng. Editorial Secretary: D. Couper, M.D. Extra Councillors: Geo. Mather, M.D., F.F.P.S.G., Wm. Findlay, M.D., Wm. Carr, M.B., Robt. McC. Service, M.B., Alexander Munro, M.B., and Jas. Dunlop, M.B.

THE MEETING OF THE ASSOCIATION OF GERMAN NATURALISTS AND MEDICAL MEN.

(FROM OUR BERLIN CORRESPONDENT.)

(Continued from p. 881.)

THE GENERAL MEETINGS.

THE last paper read at the second general meeting was a highly metaphysical one on the Neo-Vitalistic Theory, by the well-known biologist Professor RINDFLEISCH. He said that biology has of late withdrawn from mere materialism, and that its recent mode of contemplating nature, although the ancient "vital power" of the vitalistic theory has been abandoned, may with good reason be termed Neo-Vitalism. The mechanical theory has not succeeded either in clearly defining force and matter or in explaining their mutual relations. We cannot form a conception either of force without matter or of matter without force, but we do not know how they are connected together; the recognition of force as an essential quality of matter does not imply a comprehension of its nature. It is reasonable to suppose that the principle which moves the whole world is present also in any of its parts, but it is obvious that inorganic bodies do not really move of themselves without receiving impulses from outside. We must, therefore, confine our attention to animated nature. Even if we could succeed in measuring or counting the atoms concerned in every vital phenomenon we would still fail to understand the vital process itself. We must cast off the tyranny of materialism, which would make us believe that animate and inanimate objects are of identical composition and therefore of the same value for the purposes of investigation. What do we mean by the expression "life"? If we throw a stone into the air it will fall at a spot which may be determined beforehand by calculations based on the strength of our arm, the weight of the stone, &c. If we throw a bird into the air it also will come back to some part of the earth, but it can choose the place where it will alight and is independent of the impulse given to it at the moment of release. We regard the power of spontaneous movement as the characteristic sign of life, and the same principle exists even in the minutest parts of animated nature. A drop of blood from a living frog examined under the microscope at first shows a movement of the blood corpuscles, which in course of time ceases, but on warming the object it can be seen that the leucocytes change their form, and that little protuberances, like feet, emerge from the substance of the leucocytes and move actively on the glass. The movement becomes quicker and quicker and suddenly stops when the temperature exceeds a certain degree, beginning again when the source of warmth is removed and the temperature has again reached the proper point. If we compare these changes with the simple extension of an inorganic substance, a piece of copper for instance, we cannot but conclude that the living substance is able to transmute forces impressed from outside in a way which appears to us to be the result of individual selection. Not in the sense, of course, of an emancipation from the laws of nature; on the contrary, this selective power is a quality of animated matter which admits of at least a plausible explanation. We may suppose that the vital selection results from a preliminary transmutation of external impulses into tension. In this way even the strongest impulses are stopped, and if afterwards the cell or the animal makes movements they appear to the spectator to be spontaneous, although they result only from transmutation of accumulated force. Protoplasm consists of colloid substance the molecules of which by mutual attraction and by keeping their position with respect to each other are also elastic, and in this way that accumulation of tension becomes possible which is necessary for the explanation of self-determination. The distance of the molecules corresponds to the degree of tension. According to physical laws, warmth, electricity, chemical agents, &c., must influence the distance of the component molecules, and by augmenting or diminishing their potential energy may produce effects which appear as extension and contraction of the swollen colloid. But even if biology were able to give a description of all the transformations produced in a body by an external influence till an apparently spontaneous movement originates, if even we could see the atoms at work, we should not have got a knowledge of the essential underlying

Digitized by Google

principle unless some one could tell us what an atom really is. Meanwhile we may contemplate such phenomena of vital self-determination as are most like their prototype, the spontaneously moving matter. Such phenomena exist in our own body; each movement of our muscles is connected with a perception of it, which also has the important office of regulating that movement; each perception is connected with an action of the central nervous system, by which it is transmitted to the peripheral parts of the body. In all operations of the will, the intellect, and the sentient faculty there are a receptive action and a directive action, both so closely united that they seem to form one function of the mind—namely, self-consciousness—which, of course, appears to us as inseparable from self-determination. In proportion as the former increases in the more highly organised animals, so does the latter become further developed, until in man it presents itself as the essential characteristic of the genus.

The other papers read in the general meetings were by Professor ASTWALT (Leipzig) on the Mechanical Theory of the World, by Professor CREDNER on the Origin of the Baltic Sea, and by Professor VICTOR MEYER on the Problems of Atomology.

THE SECTIONS.

The following is an abstract of the proceedings in the sections.

Surgery.

Dr. HOFFA read a paper on the Treatment of Deformities arising from Hip-joint Disease. He said that as long as mobility exists these deformities are not to be treated by cutting operations, but by extension, by splints, or by Dollinger's method. If there is complete ankylosis osteotomy must be performed, but as the operations now in use shorten the thigh Dr. Hoffa has devised a new method, to which he has given the name of "oblique subtrochanteric osteotomy." He begins by separating the muscles and tendons from the trochanter to the external side of the femur, and then with a chisel severs the bone in an oblique direction. The limb is then extended so that the lower portion of the bone slides down along the upper portion, both osseous surfaces being maintained in contact. If the resistance of the muscles is too strong tenotomy must be performed before applying the extension.

Dr. LANDERER described a New Method of treating Tuberculosis by the Internal Administration of Cinnamic Acid. Experiments on animals prove that by this treatment the bacilli after the fourth month lose their virulence, and that fibroid tissue grows through the tubercles. Of 45 cases of simple chronic pulmonary phthisis without cavities treated by cinnamic acid all but 2 showed an improvement; their weight increased, their cough ceased, and the bacilli disappeared from the expectoration. Among 190 patients suffering from external tuberculosis the disease was in 155 cases situated in the bones and joints. Of these 6 died, 2 were not benefited, 8 were improved, 127 recovered, 2 would have to undergo amputation, and 10 were still under treatment.—Professor BERGMANN and Professor KÖNIG thought that tuberculosis could hardly be cured in this simple way.

Dr. NITZE gave an account of an Intra-vesical Operation for Tumours of the Bladder. His instrument consists of a sling connected with the ordinary cystoscope which may be easily introduced through the normal urethra. The surgeon in this way may remove the tumour under direct ocular inspection. After the operation the pieces of the tumour are voided with the urine. Tumours of the size of a pigeon's egg may be extirpated in this way, the bleeding being only very slight. The tumour is sometimes removed entire, sometimes in repeated sittings, and its base is energetically cauterised with the galvano-cautery. No anæsthetic is required, cocaine being sufficient. There have been 21 satisfactory cases.

Medicine.

Dr. MARTIUS discussed the Indications for Irrigation of the Stomach. They are of two kinds—positive, where the omission of irrigation would be a grave default; and relative, where the physician may use his discretion. Among the conditions belonging to the first category are acute poisoning, stagnation of the contents of the stomach from pyloric stenosis, and all cases of ileus. Under the second heading may be included carcinoma, acute and chronic catarrh, and functional abnormalities, such as hyper-secretion. In gastric neurasthenia Dr. Martius has sometimes obtained good results from irrigation.—Dr. MINKOWSKI said that he had performed irrigation for hæmorrhage from gastric ulcer, of course introducing a very smooth tube. Irrigation ought always to be done in the evening, so that the stomach may rest during the night.—Dr. LEO and Dr. RUMPF advised irrigation for the gastro-enteritis of infants

Dr. QUINCKE gave an account of the results of Puncture of the Spinal Canal, an operation which was described in THE LANCET of April 20th, 1895. He now uses an apparatus by which the pressure of fluid contained in the spinal canal may be measured. The effects are negative when the pus is too thick to flow through the cannula or when the needle has been improperly introduced. The best results were obtained in cases of serous and sero-purulent meningitis.—Dr. ZIEMSSEN confirmed the statements of Dr. Quincke, especially in cases of epidemic cerebro-spinal meningitis.—Dr. LENHARTZ said that his results had not been altogether favourable, and in several cases no fluid could be obtained although the operation was efficiently performed. In one case where eighty cubic centimetres of fluid were evacuated there was no obvious effect on the sensorium, and in another instance the patient became worse after the operation.

Dr. POSNER read a paper on the Etiology of Nephritis, in which he stated that he had made experiments on animals in order to ascertain if the bacteria in the bowels can produce nephritis by entering the circulation. Glomerulitis and epithelial necrosis follow ligature of the ileum. If matter containing the bacterium coli is injected into a bloodvessel, real nephritis ensues. Bacterium coli introduced into the healthy kidney itself is very soon excreted, but if the kidney had been previously impaired by injections of alcohol many bacillary emboli are found. Dr. Posner came to the conclusion that nephritis may arise from infection by enteric bacteria.

Obstetrics and Gynæcology.

Dr. LEOPOLD discussed the question, Is Digital Examination necessary during Confinements? He said that the position of the fœtus and the progress of the labour can be ascertained by abdominal palpation merely, and that digital examination should only be resorted to when there are abnormal symptoms. It is unnecessary when there are no abnormalities in the labour or in the condition of the mother, and the great majority of confinements should therefore be conducted without it.—Dr. FEHLING advised his audience to abstain entirely from digital examination and recommended that midwives should learn to disinfect their hands properly so as to avoid the communication of infection to lying-in women.

Dr. PROCHOWNIK described the Treatment of Ectopic Pregnancy by Injections of Morphia and gave particulars of four cases in which he had used injections of from 0·03 to 0·04 gramme of morphia into the fœtal membranes by way of the vagina. Three of the cases recovered without incident; in the fourth, which was complicated with gonorrhœa, an abscess formed and opened into the rectum. In one case the injection was made through the abdominal walls and the bowel, which was adherent to the fœtal membranes, was perforated. Although the fœtal sac became filled with pus the patient recovered after the operation. Injections of morphia ought not to be performed after the third month, and they are useless when once abortion has begun. Injection through the vagina is preferable to an abdominal operation except in cases of acute perimetritis or gonorrhœa.—Dr. FEHLING was of opinion that ectopic pregnancy may be compared to a malignant growth and therefore requires operation.

Dr. FEHLING read a paper on the Treatment of Prolapse of the Uterus. He recommended that as a precaution women ought to stay in bed a somewhat long time after confinement. In slight cases pessaries ought to be tried first, and in elderly women, where operation is contraindicated, a bandage should be applied, but in all other cases operative measures are advisable. To avoid relapses the old vagino-perineal plastic operation ought to be combined with Olshausen's ventro-fixation or Dührssen's vagino-fixation. Total removal of the uterus is followed by only 7 per cent. of relapses, but it mutilates the woman and is attended by a mortality of 10 per cent.; it ought, therefore, to be reserved for aged patients and cases of exceptional severity.

Physical and metaphysical questions were predominant in this year's proceedings, whilst practical medicine was almost exclusively confined to the sections. It is said that the committee is preparing to make a change in the arrangement of the annual programme by allowing only two general

Digitized by Google

meetings and by extending the work of the special sections. No doubt the organisation of the association is once more in need of reform. The next meeting will be held at Frankfort.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

The Opening of the Medical Institution: Winter Session.

THE first meeting of the Liverpool Medical Institution for the present session took place on the 10th inst. Mr. Chauncy Puzey, the President, gave a very interesting address to the 140 members present. He began by paying a graceful tribute to Sir Joseph Lister, alluding to his retirement from active duties at King's College Hospital, and to the presentation to him of his portrait by his colleagues and past pupils. Mr. Puzey then referred to the time, now thirty years ago, when Sir Joseph (then Mr.) Lister began his experiments with carbolic acid in the treatment of abscesses and compound fractures with a view to diminish the terrible pest of pyæmia, at that time the great enemy of successful surgery. Mr. Puzey next alluded to the coincidence that just at that time he came to Liverpool as junior house surgeon to what he called the old Royal Infirmary, but which it would be more correct to style the second infirmary. The first one, the real old infirmary, must ever be memorable to surgeons as the scene of Park's great triumph in conservative surgery. The contrast between the surgical treatment of those days and of the present, the successful results of present-day surgery and our indebtedness to Sir Joseph Lister were next noticed, and as he had had the opportunity of trying or watching their results Mr. Puzey decided to give a slight sketch of the earlier history of the antiseptic movement, which might be described as terminating with the decline and fall of the carbolic spray. When he came to the second infirmary, which, completed in 1824, was, as he observed, new compared with Guy's Hospital, he was struck with the comparative freshness of the atmosphere of the wards, and subsequently with the smaller rate of mortality after major operations; but the mortality, especially from pyæmia, was such as would now be considered terrible. Primary union after amputations was so rare as to be considered remarkable, and suppuration was always present in such operations as the removal of tumours or ligature of the larger arteries. After remarking on the different condition of affairs at the present time, Mr. Puzey passed on to detail Lister's work as described by himself, as practised at first, and as practised now. He alluded to the late Mr. William Jackson Cleaver of Sheffield as having been house surgeon at the Liverpool Infirmary rather more than twenty years ago, of his having been Lister's house surgeon at the Edinburgh Royal Infirmary, and of his having been successful in his attempt to do away with pyæmia. Allusion was also made to Mr. H. D. Farnell, now of Eastbourne, senior house surgeon at the Northern Hospital when Mr. Puzey was surgeon, and who practised the Listerian method with great success. After giving further proofs of the great results following the antiseptic treatment Mr. Puzey concluded as follows: "For the present, gentlemen, we can look forward with pleasurable anticipation to the time next year when we shall have him in this city as the President of the British Association. Then I am certain that from no section of our citizens will he receive a more hearty welcome than from the members of the Liverpool Medical Institution."

The late M. Pasteur.

Mr. Puzey made the following graceful allusion to the late M. Pasteur: "Pasteur has been taken away from the scenes of his useful work; but while the whole civilised world has heard of his departure with respectful regret, his own country has accorded him the honour of a State funeral—as usual, in such matters, setting an example in its tribute to the memory of great scientists and professional men which our own country might do well to follow."

Bequests to Liverpool Hospitals.

The following institutions will benefit to the amount given against each by the will of the late Mr. Bernard Vincent Hall of Liverpool: the Royal Infirmary, £5000; Northern Hospital, £2500; Royal Southern Hospital, £2500, and the Ladies' Charity and Lying-in Hospital, £1000.

The Northern Hospital and Cases of Abdominal Surgery.

Within a period of nine days three persons have been admitted into the Northern Hospital suffering from severe abdominal wounds. The first was a man aged thirty-four who was stabbed while trying to separate a husband and wife. He was admitted on the 5th inst. under the care of Mr. Arthur Wilson suffering from a wound one and a half inch long a little below and to the right of the umbilicus. About three inches of small intestines were protruding, but there was no injury to them or to the omentum. The intestines were thoroughly washed and returned, and the patient is now doing well. The second case was that of a man aged twenty-eight, who was admitted on the 9th inst. also under Mr. Wilson. He had jumped or been pushed through a window fifteen feet from the ground. When admitted, after being three-quarters of an hour on the pavement, the ascending and transverse colon with about three feet of small intestines were found protruding through an incision about three inches long in the right hypochondrium. An incision was found about half an inch long in the transverse colon, from which fæces were passing. All the intestines and omentum which protruded were black and dirty. The wound was sutured, the bruised omentum removed, everything well washed and flushed, and then returned. The patient succumbed on the evening of the fourth day. The third patient, a woman aged thirty, was admitted on the 14th inst. under Mr. Puzey with a small transverse wound through which several coils of bowel were protruding. Two wounds, one dividing half and the other the whole circumference of the gut, were closed with Lembert's suture. On pulling out more gut a portion was found transfixed in three places within about three or four inches, the mesentery also being badly cut, while several arteries were spouting. The whole of this piece was excised and the ends approximated by means of Murphy's button. On enlarging the wound upwards and downwards to return the intestine it was found that the abdominal cavity contained a quantity of blood, while the pelvis was full of clot. On flushing this away the finger passed into a cut in the fundus of the uterus; the abdominal wound was extended downwards, and the wound in the uterus (through which protruded the cut cord of a fœtus in a very early stage) was closed by deep suture. The "toilet of the peritoneum was made" and the abdominal wound was closed in the usual way. Twelve hours later the woman was rallying well.

Annual Dinner of the Medical Institution.

The annual dinner in connexion with the Medical Institution was held at the Adelphi Hotel on the 5th inst. Over 100 members and guests were present. Advantage was taken of the circumstance that Jan. 13th last was the "silver wedding" of Hospital Sunday in Liverpool to make special allusion to the clergy and ministers in connexion with the medical charities. The Rev. J. Bell Cox and the Rev. John Watson, both prominent members of the Hospital Sunday Committee, the latter being also Honorary Secretary, responded.

Oct. 15th.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Extension of the Manchester Royal Infirmary.

THE report of the sub-committee was presented yesterday to the grand committee appointed in March last to consider the question of the increased accommodation long required by the infirmary. The problem was how to provide 120 more beds on the present site without materially encroaching on the unoccupied space. The sub-committee was not unanimous, and a minority report was also presented. Schemes for providing this accommodation by lateral extension of the present building and by adding another storey had already been considered and rejected. The possibility of obtaining this accommodation by altering the internal arrangements, by removing the nurses from the home within the grounds, and by removing also the out-patient department and the laundry, were considered, and the conclusion arrived at was that, "as it was opposed to all modern experience to locate the nurses' home elsewhere than within the precincts," it should not be removed, and that the removal of the laundry and the out-patient department would not give the needed accommodation. The decision

Digitized by Google

of the sub-committee was that "only by rebuilding would it be possible adequately to provide, in a fit and proper way, the requirements of an infirmary brought up to date scientifically with every latest improvement, and otherwise worthy of the city of Manchester." The pavilion plan was unanimously considered to be the most suitable, and competent authority stated that there would be no difficulty in constructing a pavilion hospital fulfilling all the conditions required. "They would, however, ask to be allowed respectfully to suggest that their decision be accepted with as little delay as possible by the grand committee, and be immediately thereafter submitted to the trustees for ratification." The chief points in the minority report were as follows: "They do not see the necessity of building an entirely new hospital," believing that everything required can be provided by a modification of the existing building. They are of opinion that the cost of a new building cannot be less than, and will probably exceed, £200,000. They consider that by adding a storey (a plan already rejected), and by making minor alterations, all the "reasonable" accommodation required could be obtained for £40,000 or £50,000. The two reports having been read, resolutions were adopted to the following effect: That the signatories of the majority report be requested to obtain full plans and elevations, and evidence from experts in hospital buildings and others as to the practicability and efficiency of such plans, and an approximate estimate of costs; that a further sub-committee be appointed to obtain the opinion of experts and others as to the building of a new supplementary hospital elsewhere to provide the additional accommodation required, with estimates of costs &c., and to report as to the alterations required in the present building "to bring it up to date and to make it as efficient as possible according to modern ideas"; that the signatories of the minority report be asked to give full details of this scheme, prepare plans, &c., with all the powers given to those who signed the majority report.

Oct. 15th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Scarlet Fever in Edinburgh.

THERE is a considerable epidemic of scarlet fever in Edinburgh. In the City Hospital there are 359 patients, the hospital being so crowded that accommodation has to be made elsewhere for some cases, and there is a probability that the disused hospital in the Canongate may have to be reopened. The extent to which the City Hospital is used is noteworthy, for it shows the confidence the public have in it now as compared with the feeling when it was first opened. In this connexion it may be stated that the ground purchased as a site for the new City Hospital has been examined by a body of officials, and the part upon which the building is to be erected has been determined.

Milk-supply and Infectious Diseases.

At a meeting of the Edinburgh Town Council a question was asked by one of the members as to the powers they possessed to examine all cows whose milk is sent into the city. The question was asked in view of the connexion which had been sometimes proved to exist between the milk supply and epidemics of infectious diseases. The town clerk, in reply to the question, stated that the magistrates and council had ample power to appoint a qualified veterinary surgeon to inspect and examine all cows in byres outside the city whose milk was sold within the city.

Edinburgh Royal Infirmary.

The beginning of October marks the opening of the winter's work in the Royal Infirmary. At this date the resident physicians and surgeons are changed. On Tuesday the clinics were begun, and all the wards are now in charge of their respective senior physicians. Dr. Ernest E. Maddox has been appointed an assistant ophthalmic surgeon, and Dr. George Mackay has been made a full ophthalmic surgeon.

Fever Hospital in Hawick.

The corporation of Hawick have wisely determined to try to arrange terms with the district committee with a view to the provision of a joint hospital for infectious diseases for the town and district. It is thought that only ten or twelve beds will be necessary.

Opening of St. Andrews University.

The winter session of the United College was opened by an address by Principal Donaldson. He said that the administration of the financial affairs of the University was at a dead-lock, and as that was due to legislation and the difficulty of interpreting it, it was the duty of the Legislature to intervene and find a way out of the dead-lock. Regarding external organisation and appliances there was nothing but prosperity and success to report. Within seven or eight years five new buildings had been erected at a cost of £20,000. One of the new buildings was to be specially devoted to women students, and to bear the name "University Hall." Seven scholarships had been instituted, each of the annual value of £100. He said that when all the scholarships were arranged they would have the largest number of scholarships and the most complete distribution of them of any university in Scotland.

Glasgow Southern Medical Society.

At a meeting of this society on the 3rd inst. the following gentlemen were elected office-bearers for session 1895-6: President, Alexander Rankin, M.D.; Vice-President, David Tindal, M.D.; Treasurer, J. C. Edmiston, M.D.; Secretary, T. W. Jenkins, M.D., 1, Newark Drive, Pollokshields; Editorial Secretary, J. G. Wilson, M.B.; Seal-keeper, David Couper, M.D.; Governor of Victoria Infirmary, James Dunlop, M.D.; Court Medical, John Brown, M.D., A. Napier, M.D., J. Lindsay Steven, M.D., T. Lapraik, M.D., and T. Walls White, M.D.; Extra Members of Council, C. E. Robertson, M.B., T. Richmond, L.R.C.P., and G. W. Thomson, M.D.

Royal Hospital for Sick Children, Glasgow.

The directors of the hospital have made the following appointments: Walter K. Hunter, M.B., and Alice J. McLaren, M.D., B.S., to be extra-physicians to the dispensary; L. R. Sutherland, M.B., to be pathologist; Jno. F. Barr, M.B., assistant house surgeon; and Samuel English, M.B., clinical assistant at the dispensary.

The Health of Dr. J. B. Russell of Glasgow.

Though Dr. Russell has been able for a time to return to his duties as medical officer of health it has been deemed advisable that he should not undertake the heavy work of the winter. He has therefore obtained six months' leave of absence from the town council and intends to winter either the south of England or the Channel Islands.

Hospital for Infectious Diseases for Dumbartonshire.

The Dumbartonshire County Council has for some time been endeavouring to find a site in the western division of the county suitable for the erection of a hospital for the reception of infectious cases. Recently there has been an outbreak of scarlet fever in the Vale of Leven, and this appears to have brought matters to an issue, for the council has now purchased a piece of ground situated midway between Renton and Alexandria, and here intends to erect a hospital adequate to the requirements of the district.

Measles Epidemic at West Calder.

Owing to a severe outbreak of measles at West Calder the public school has been closed by order of the school board. The epidemic has spread rapidly and nearly 400 cases have been notified.

Medical Appointments.

Mr. Alfred Young, M.B., has been appointed surgeon to the Central Dispensary, Glasgow, and Mr. Jas. Connal, M.B., has joined the staff of the Grove-street Dispensary, Glasgow.

Veteran Volunteers.

An anniversary of considerable interest was celebrated at the Royal Cottage, Loch Katrine, on the 12th inst. On Oct. 14th, 1859, the Queen formally opened the Loch Katrine water-supply of Glasgow, and on that occasion Her Majesty saw for the first time a body of her citizen soldiers under arms, her guard of honour being supplied by the then recently enrolled Glasgow companies. It has been the custom year after year for the surviving members to celebrate the anniversary, and this year it was decided to meet at Loch Katrine for the thirty-sixth anniversary. No less than thirty-four members of the Old Guard spent the day together in the Trossachs, and in the afternoon dined together in the Royal Cottage. The chair was taken by Brigade-Surgeon Dr. James Dunlop, and amongst the other "veterans present were Surgeon-Lieutenant-Colonel

Digitized by Google

J. G. Cumming, M.D., and Alex. Patterson, M.D. After dinner a telegram was despatched to Her Majesty respectfully expressing the feeling of loyalty which still keeps the Old Guard together.

Aberdeen University: the Inaugural Celebrations.

All the arrangements for these celebrations, which will take place next week, are nearly completed. The new clock and bell have been safely located in the Mitchell Tower, the organ is nearly finished, and the rest of the work is being pushed on apace. An interesting part of the proceedings will be the presentation to Mr. C. W. Mitchell, together with an address, of a gold medal commemorative of his father's large share in this big extension scheme. The medal will cost about £100, and replicas in bronze may be had for 7*s.* 6*d.* Mr. Mitchell will also receive an address from the students acknowledging the special interest that Dr. Mitchell took in the students, as shown by the magnificent Union erected at his expense. A large number of graduates have intimated their wish to be present, and there is every prospect of the celebration being a success. The University Court have now decided to proceed with the north tower, terminating the north wing. Some weeks ago it seemed likely that this part of the scheme would have to be deferred for lack of funds. The tower is to be a square one, 32 ft. wide on each face, and with a total height of 120 ft., and its design will harmonise well with the Mitchell Tower and the rest of the buildings. It will accommodate on the ground floor the sacrist's house, on the second floor will be the Faculty and University Court-room, and on the third floor will be provision for the Secretary of the University Court.

The Health of Aberdeen.

The zymotic diseases notified last week were—scarlet fever, 21; whooping-cough, 40; erysipelas, 8; puerperal fever, 1; membranous croup, 1; total, 71, being 27 cases more than the former week, due to a considerable increase in scarlet fever and whooping-cough.

Oct. 15th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

A Pathological Institute for Dublin.

THE usual addresses inaugurating the commencement of the medical session were delivered at the Meath and St. Vincent's Hospitals on the 12th and 15th inst. Mr. E. Lennon, physician to the Meath Hospital, devoted a large portion of his address to a matter which has been more than once alluded to in the pages of THE LANCET—that is, to the necessity which exists in Dublin for a pathological and bacteriological institute. It was suggested that such an institution might be established in connexion with the Royal Academy of Medicine and based upon the lines of that already founded by the Royal Colleges of Physicians of London and Surgeons of England. The President of the Royal College of Physicians, who occupied the chair, said, in proposing a vote of thanks to the lecturer, that, while admitting the great importance of the matter, it would be a mistake to underrate the difficulties as to its accomplishment, more especially those of a pecuniary nature. The President of the Royal College of Surgeons, in seconding the vote, expressed himself as even less sanguine as to the success of the proposal made by Mr. Lennon. Sir William Stokes, on the other hand, said that he did not take such a dismal view as to the difficulty and want of unanimity in carrying out the project of the lecturer, which if successful would be of the greatest benefit not merely to the cause of science, but to the cause of humanity as well. He believed that when the lecturer's words were thought over, and his suggestions contemplated, the feasibility of the plan would not appear, as it did to their chairman, of a very Utopian character. He believed that with an earnest effort of the profession generally this great philanthropic purpose might be accomplished.

County Monaghan Infirmary.

I understand that the governors of the Monaghan and Cavan Lunatic Asylum have agreed to purchase the old Monaghan Infirmary premises and grounds at a cost of £1000.

Omagh District Asylum.

Owing to the overcrowded state of this asylum the governors have been considering the advisability of building a new wing, and at their meeting on Oct. 10th a communication was read from the Board of Control in Dublin sanctioning a loan of £35,000 for the purpose of carrying out the necessary changes in the way of alterations and additions to the institution. It is expected that the building will be completed and ready for occupation at the end of March, 1898.

New Mortuary in Belfast.

The Corporation of Belfast have just erected a new mortuary to replace the old morgue in Victoria Square. The new building is situated at the end of the Sand Quay on the river Lagan, a site obtained by the Corporation by their Act of 1878, when they purchased the rights of the foreshore from the late Marquis of Donegall. The mortuary is entered from the Laganbank-road, but the plans have been so drawn that none of the windows look on to that thoroughfare. There is a yard one side of which forms by a wall the boundary next the river, and a door placed in this wall provides a means of receiving bodies which may be discovered in the Lagan river, and by this means they will not need to be conveyed through the city. There is a house near the entrance gates for the van, which also affords space for the storing of coffins. To the right of this is the building proper, in which there is a waiting-room for jurors and an attendance-room, two mortuaries (one for infectious the other for non-infectious cases), a post-mortem room, and a dead-house, with lavatories for the use of medical men and others engaged. All the floors are of Limmer asphalt on cement concrete, and the walls are lined with white, glazed tiles. All the rooms are well heated and ventilated and supplied with water, the pipes being exposed on the face of the wall to permit ready access in case of leakages or gas escapes. The post-mortem room is fitted with Jennings's patent revolving dissecting-table and two Jennings's patent lavatory basins with hot and cold water, all the taps and wastes being operated by the foot, so that, without the hands being used at all, the water can be turned on or off. The shelves in the room are of plate-glass on enamelled iron trestles, and the benches on the mortuaries are of slate. The windows are of plate-glass, and are so arranged that, if deemed advisable, a body can be viewed by a jury without the latter entering the actual apartment in which it lies. The whole building has been designed by Mr. J. C. Bretland, the borough surveyor, upon whom it reflects the utmost credit, being now the best mortuary in any city in Ireland or, indeed, the United Kingdom. The medical members of the Belfast corporation, Alderman Graham, M.D., and Councillors O'Neill, M.D., and Bigger, M.D., have greatly helped the surveyor by valuable hints.

The Outbreak of Typhus Fever at Ardboe, county Tyrone.

At a weekly meeting of the Cookstown guardians, held on Oct. 12th, it was reported that all the cases from Ardboe were in hospital except one, and those were convalescent. Eight hospital patients were confined to bed. On that morning a man had been brought in, but as the assistant nurse was suffering from the disease and no other nurse available it was only possible to bring him by getting his wife to accompany him in the ambulance. The medical officer was empowered to get a nurse from the Belfast union if required, and to have the ambulance properly ventilated. Mr. Burgess and the relieving officer have attended in all the houses where there had been typhus fever and burned the bedding, and payment has been made for the things destroyed. As showing the terror existing in one district Mr. Burgess and the relieving officer, assisted by two boys who were only just recovering from the fever, had to coffin a man and bury him themselves; no one could be got to assist except the driver of the hearse and of the car. The medical officer was obliged to change all his clothes after being at Ardboe as there were no means of disinfection.

The Duties of Medical Officers, Masters, and Matrons in Irish Workhouses.

The Local Government Board have declined to hold a sworn inquiry in reference to this point as requested by the Ballymena board of guardians.[1] The inspector had an interview with the officers concerned. The master, the Local Government Board think, had exceeded his duty in transferring the lunatic to the lunatic wards without consulting the medical officer, and they do not think the

[1] THE LANCET, Oct. 5th, 1895.

Digitized by Google

master should dispute the authority of the medical officer in questions affecting the classification of sick inmates.

Belfast Lunatic Asylum.

The overcrowded state of this asylum is becoming a very serious question for the governors to deal with. There are 286 cases now resident beyond the normal accommodation, and while the female division accommodates 180 cases, there are now 277 resident. The matter has been left in the hands of the accommodation committee; some think room could be had at the workhouse, others at the model farm or at the superintendent's house. At the meeting of the governors held on Oct. 14th a resolution was passed urging the Board of Control in Dublin to expedite matters in reference to the preliminary arrangements, submitting suggestions and recommendations to architects for their competitive plans for the new asylum at Purdysburn. A deputation from the Board of Control, it is expected, will shortly visit Belfast to discuss details with the governors of the Belfast Asylum.

The Guardians of the Cork Union and the Establishment of a Pasteur Institute for the Treatment of Hydrophobia.

The Cork guardians have from time to time sent patients bitten by rabid dogs to the Pasteur Institute in Paris, and they have been considering whether they ought not to urge the Government to establish a similar institution in London. At their last meeting Mr. Harding, dispensary medical officer of Ballincollig, presented a lengthy report on the subject of Pasteur's treatment, in which he urged that it was a success. Dr. Magner, one of the guardians, on the other hand, expressed grave doubts as to whether any definite conclusion could be arrived at. At the last meeting of the guardians Mr. Harding presented a further report, accompanied by letters he had procured from about a dozen of the profession in the city. These gentlemen generally endorsed Mr. Harding's views, though one or two expressed their opinions rather guardedly. Dr. Magner pointed out that Mr. Harding had not sought the opinion of the medical officers of the city dispensaries, under whose care persons suffering from dog bites frequently came in the first instance, and he added that those gentlemen's opinions would not correspond with Mr. Harding's. He also pointed out that some of the statistics on the subject were somewhat misleading. The discussion was a very interesting, academic one, very suitable for a medical society or the pages of THE LANCET, but I fear a little bewildering to the average rural guardian. The guardians finally passed a resolution asking the Government to take steps for the establishment of an institute in London, but at the instance of Dr. Magner they added that they would not approve of the rates of the Cork Union being requisitioned for the purpose.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The late Baron Larrey.

THE above-named surgeon, who died last week in his eighty-seventh year, at Bièvres, near Versailles, was principally known to the world as the son of his father, the great surgeon of Napoleon the First's campaigns. His father's influence procured him admission, at an early age, into the medical department of the army. We then find him a *Chirurgien-élève* in 1828, *Sous-aide* in 1829, *Aide-major* in 1832, and *Chirurgien-major* in 1841. Graduating as an M.D. in Paris in 1832—the year of the cholera epidemic—he was placed in charge of the cholera wards at the Pitié Hospital. But he soon resumed active regimental service, and we next find him—now an *Aide-major* (assistant surgeon)—at the Siege of Antwerp. Here he earned his first decoration—that of Chevalier of the Order of Leopold. In 1835 he successfully competed for the post of Professeur-agrégé (de Chirurgie) of the Paris Faculty. In 1841 he was appointed to the chair of Surgical Pathology at the Army Medical School of Val-de-Grâce. Nine years later he exchanged the chair for that of Clinical Surgery. No sooner were the Bonapartes restored to power than he was appointed Surgeon-in-Ordinary to the Emperor, but it appears that the confidence reposed in his illustrious father by Napoléon le Grand was not inherited by him, for the great Emperor's nephew had hardly ever recourse to his services. He acted during the Italian campaign of 1859 as *médecin en chef* of the army, and he then distinguished himself by—what was at that time an innovation—organising the transport of the wounded by rail. In 1867 he was promoted to be *Inspecteur du Service de Santé Militaire*, and was at the same time decorated with the *plaque* of Commander of the Legion of Honour. Since 1850 he had been a member of the Academy of Medicine, and later he was admitted to the membership of the Société de Chirurgie. Of both corporations he had acted as President. Finally, in 1867, he became a *membre libre* of the Académie des Sciences. He wrote a number of interesting works, which, with about 100 contributions to journals, constitute the sum total of his professional life-work. At the fall of the Empire he retired from the army, but he represented for several years at the Chambre des Députés the *arrondissement* of Bagnères de Bigorre as a Bonapartist. In his old age he occupied himself in relating, in his book entitled "Madame Mère" (Napoleon I.'s mother), the doings at the Imperial Court. The work is said to have fallen flat, the craze now raging for the anecdotal history of the Napoleonic era being then unknown. The halo surrounding his name procured him quite exceptional consideration at the learned societies of which he was a member. His attendance at the Academy of Medicine was, up to quite a recent date, most regular, and great respect was paid to his utterances. His venerable and picturesque appearance was in large measure accountable for the privileged position he occupied. Someone very aptly compared him to *un portrait peint par Gérard*. His "bringing-up" would naturally have the effect of fostering within him all his ultra-conservative instincts, and his respect for rigid professional and academic *étiquette* was abundantly evident on the occasion of the communication made to the Académie de Médecine by Professor Brouardel regarding the state of health of Dr. Cornelius Hertz. His views on surgery remained to the last conservative. But although he will, as a surgeon, leave behind him no trace, his urbanity, his old-world politeness of *un homme de cour*, will for a long time be missed.

Treatment of Dacryocystitis.

M. Duclos[1] speaks in eulogistic terms of the curative effects of fluorol in the above-mentioned affection. This salt (fluorol, or fluoride of sodium) is bluish-white, odourless, of a salty flavour, and is soluble in twenty-five parts of its weight of water. A 1 or even 0·5 per cent. solution prevents the development of pyogenic organisms. Fluorol is to be preferred to corrosive sublimate (which is sixteen times more toxic), silver nitrate, permanganate of potassium, formal, &c., because its introduction into the lacrymal apparatus is not painful, and because, further, it is distinctly more beneficial. Dr. Lagrange, in whose clinic at Bordeaux the new treatment has been extensively employed, opines that fluorol proves more efficacious than sublimate &c. because it does not coagulate albumin and because a protecting envelope is thus not provided for the germs. M. Duclos and Dr. Lagrange state that cases of dacryocystitis are very quickly improved, and often completely cured, by injections of a 0·5 per cent. solution of fluorol.

Hospital Districts in Paris.

Yesterday the new regulations concerning the admission of patients into the Paris and the department of the Seine hospitals came into operation. Under the new arrangement non-paying patients can only be received into the hospital specially attached to their *circonscription*, the privilege formerly enjoyed by them of choosing the institution in which they desired to be treated being thus abolished. There are, however, certain exceptions to this rule. Thus, children from any quarter will continue to be admissible into the two children's hospitals (Enfants Malades and Trousseau) as also into the children's surgical wards of the Tenon Hospital and the orthopædic wards of the Hôpital des Enfants Assistés. Patients suffering from certain special diseases will continue, as heretofore, to be admitted into special hospitals—namely, St. Louis, Ricord, and Broca Hospitals for skin diseases and syphilis; Salpêtrière Hospital for diseases of the nervous system; Lariboisière Hospital and the Hôtel-Dieu for eye affections; Necker Hospital for diseases of the urinary apparatus; Cochin Hospital for gynæcological surgery; Aubervilliers and Bastion 29 Hospitals for infectious diseases. In case of accidents the sufferers will be received into the nearest hospital.

ROME.

(FROM OUR OWN CORRESPONDENT.)

An Epidemic of Infanticide.

CERTAINLY people "sup on horrors" in the evening press of Italy. The case of infanticidal mania to which I lately drew attention has been followed by others on a much more extended scale, but before proceeding to these let me pursue the former to its conclusion. The malefactor in question (Callisto Grandi, it appears, is his name) is no longer to be allowed to return a free agent to the scene of his murders. Popular indignation made the step impossible, and so the authorities relegated him provisionally to the Muratte, the well-known Florentine prison. From this an attempt was made to transfer him to the Pia Casa di Lavoro (an establishment for the detention of ex-criminals on whom industrial task-work is imposed), and on his way thither he was followed through the streets by an ever-increasing crowd, which commented freely on his extraordinary cranial malformation and his unmistakable look of "dangerous imbecility." A first halt was made at the Questura (police-office), where, it having been ascertained that the Director of the Pia Casa had peremptorily refused to admit him, he was confined in a strong room. By this time, however, medical opinion as to his mental incapacity prevailed; at last, "at long last," says a Florentine contemporary, he has been recognised as "a "dangerous imbecile" or "irresponsible delinquent," and from the Questura he has been finally consigned to the Manicomio (lunatic asylum) of San Salvi. Had he been properly dealt with in the stage of puberty or even earlier, as Lombroso recommends, his diseased development would have been demonstrated, possibly rectified under treatment, or, if found irremediable, he would have been placed under surveillance such as would have made his crimes impossible. The deplorable fact remains, however, that his case is an all too common one, there being hardly an aggregation of Italian youth in which potential malefactors of the Grandi type are not to be found. The army, indeed, has many of them, as the recent wholesale murders committed by epileptoid subjects in barracks have so painfully attested. And now, when one "irresponsible delinquent" has finally been acknowledged to be such and detained in an asylum, we are startled by an infanticidal outbreak of appalling cold-bloodedness — twenty-three children poisoned by one of those semi-lunatics who pose as "witches." At Aderno, in the province of Catania in Sicily, a woman thirty-three years of age, Gaetana Stimoli by name, made it a practice to allure little children to her den with sweatmeats, after which she gave them a drink of wine containing undiluted phosphoric acid. The victims barely got home when they were seized with agonising pains, in which they died. The woman, having been arrested, at first denied her guilt, but then made a full confession, from which it appeared that, having lost two children of her own, she believed their death had been caused by incantation—"erano stato stregati" (they had been bewitched) was her expression—and to avenge them she poisoned the children of others! The woman's den was minutely searched and found to contain all the armoury or "stock-in-trade" of witchcraft, phosphorus included, while at the necropsy of her victims the evidence of poisoning by phosphoric acid was fully made out. The incident has created a profound impression throughout the kingdom, where similar cases (one victim having been boiled to death in a cauldron containing so-called "medicinal" herbs) are reported from nearly every province. The public are gradually becoming aware that Italy's expensive and ineffectual penal system is one gigantic illustration of "beginning at the wrong end," and that some such educational system as that which her medico-psychologists recommend can alone protect her from the homicidal explosions by which her daily life is periodically saddened.

The White Cross.

On the lines of the Red Cross, an association has sprung up in Italy for the relief of the civilian who from illness or accident has had to suspend work. A charitable institution designed mainly for the very poor, it had its origin in February, 1886, by which time, in Rome especially, the influx of labourers to assist in the reconstruction of the city had multiplied the contingent of poor patients. Under the name of "La Croce Bianca Italiana" it chose as President the Commendatore Luigi Pagliani, Professor of Hygiene at Turin, now Director-General of Public Health for the kingdom, and as Vice-Presidents the Commendatore Professor Achille Ballori, Sanitary Director of the Roman Hospitals, and the Advocate Umberto Dal Medico. On the council these gentlemen are assisted by the Commendatore Pietro Mariotti, Signor Tondi, member of Parliament, and Professor Gualdi, head of the "Ufficio Municipale" of Rome. So organised, the Croce Bianca has at its disposal a well-disciplined corps of young volunteers, male and female, equal to any duty in picking up and transporting the victim of an accident or the "wounded soldier of industry," administering "first aid" in urgent cases and tending or nursing them afterwards in hospital. Nearly eleven years old, the institution is a daily developing one, in harmony with the expansion and subdivision of the army of labour, and has stimulated the organisation of others, the Croce Verde (green cross) and the Croce Turchina (blue cross), also humanitarian in their design and medical, or quasi-medical, in their *personnel*. At Turin, where the association has taken vigorous root, an exhibition of its "armamentarium"—cars, portable chairs, stretchers, surgical appliances, materia medica and therapeutic adjuvants—has lately closed after drawing crowds of interested and appreciative visitors. Amid much that calls for reprehension, or even grave censure, in her institutions, Italy, "the mediæval mother of medicine," is laudably active in humanitarian work, and her White Cross associations, following up, or rather extending, that Red Cross Society of which she justly claims the maternity, are so many steps towards a goal at which all civilised countries ought to aim.

Oct. 13th.

PUBLIC HEALTH IN BRISTOL.—The expenditure in the department of the sanitary authority for the six months ending September, 1895, is as follows: Medical officer's department £2396; hospital expenses and medical attendance, £881; port sanitary account, £428.—The present number of the *Bristol Medico-Chirurgical Journal* congratulates the medical officer of health (Dr. D. S. Davies) and his assistants on the very satisfactory reports that have just been published and says: "The public of our city should be made acquainted with the fact that, though our sanitary rate may vie with that of most towns for amount, we can boast of being not only one of the healthiest towns in England, but in the world."

SOCIETY FOR THE STUDY OF INEBRIETY.—A meeting of this society was held on Oct. 3rd, and the president, Dr. Norman Kerr, in opening a discussion on the proposed Probationary Curative Detention of Inebriates, and others deemed to be insane, said that at present many inebriates and other persons were certified as lunatics and sent to asylums for the insane, who might have been otherwise cured under a better legislative state of things. The rich could now enter a lunatic asylum as voluntary boarders without certification of lunacy, but the poor could not avail themselves of this provision. The only chance of the poor escaping certification, even if only temporarily insane for a few weeks or less, lay in their recovery during the three days before a justice decided on their mental state, in most cases, or during the fourteen days in a few cases. Some were cured within the shorter and some within the longer term while thus attended and looked after (kindly and considerately, as Dr. Kerr had seen in some metropolitan workhouses). But, successful as the result was, how much more successful would it have been if the patients had been in a special temporary institution set apart for the mentally afflicted in an early stage, away from the hundreds of able-bodied and infirm pauper inmates, and with special equipment and ample grounds for the treatment of the insane. A good name would be "Hospital for the Treatment of Mental Disease." If at the end of six or eight weeks the patients were not cured of their insanity, then they might be certified as insane and transferred to an asylum. He ventured to predict that in twenty years or so more there would be: (1) probationary curative mental hospitals; (2) asylums not in one block, but in a number of smaller buildings, as in some American asylums; and (3) mental convalescent homes, where the discharged from the asylum could be received for a few weeks, to render the re-entrance of the convalescent into the world less trying, a work to some extent attempted at present by the excellent After-Care Association. Mr. Parker Young, Dr. Longhurst, Dr. Smith, and Dr. Usher approved of the suggestions.

Obituary.

SIR THOMAS CRAWFORD, K.C.B., LL.D., M.D. EDIN., F.R.C.P., F.R.C.S. IRELAND.

HONORARY SURGEON TO THE QUEEN.

THE news of Sir Thomas Crawford's death on the morning of Saturday, the 12th inst., will have been universally received by the officers of the department of which he was the late Director-General and by a very large number of his friends and acquaintances with much sorrow, but by all who had the honour and privilege of knowing him intimately it will have been received with profound regret. A very able, capable man, and a thoroughly upright gentleman, who long held high and responsible posts in the department over which he was ultimately presiding when he retired from the service in May, 1889, has passed away—a man of generous, hospitable, and sympathetic nature, of fine presence, noble character, and of great intellectual capacity, with a departmental experience and a knowledge of military organisation and detail, and a power of work, of which very few indeed could boast. The late Sir Thomas Crawford was not by any means a rich man, and he had a large family, but he was nevertheless most charitable. He strove in this way and by his life, his influence, and his example to promote every good work. Many of his benevolent acts were known to his friends, but some were only known to himself. Among the sad experiences of life it too often falls to the lot of earnest men of elevated character to have to undertake tasks of extreme difficulty and to be misunderstood, and the late Director-General, no doubt, had his trials in these respects. No man had held higher or more responsible positions in the department, or enjoyed a greater popularity or a higher reputation for ability, soundness of judgment, and integrity of purpose, than did the late officer when he was selected for the direction of the Army Medical Service, but he assumed the post in very troublous times. He had soon after his appointment as Director-General to vindicate his service from the unjust aspersions which had been brought against it in Egypt in 1882, which he successfully did with singular ability, winning the esteem and respect of all impartial men. This was succeeded by an enormous amount of work and responsibility in making all the medical arrangements for the campaigns that subsequently followed in that country, with the result which may be briefly summarised by stating that from the first to the last expedition successes were obtained of a surgical and medical kind that had probably never before been achieved in warfare. Then came the question of military rank and titles, about which Sir Thomas Crawford most sincerely entertained strong convictions. He held, as everybody did, that as the military service formed a necessary and integral part of the military machine its officers must be provided for and adequately recognised and respected in every way, their rank and positions being definitely fixed upon a sound and secure foundation. As regards the question of titles, however—such as major-general, colonel, captain, &c.—he considered that this was an undignified position to take up and likely to prove detrimental to the true interests of a medical service. In an obituary notice it would be quite out of place to discuss the merits of this matter, but there is no doubt that the naval medical service and many able and experienced men of the military service were of the same opinion, and some still think that he was quite right and that the object in view could have been better attained than it was. Be this as it may, that Sir Thomas Crawford was sincere and conscientious in the course he took—the wisdom and correctness of which he maintained to the last—there can be no doubt whatever.

SIR THOMAS CRAWFORD, K.C.B., LL.D., &c.

Sir Thomas Crawford was a North of Ireland man and was born in 1824, and was consequently seventy-one years of age at the time of his death. He was educated at the University of Edinburgh, where he took his degree of M.D., and was subsequently made an Hon. LL.D. of the same university. He entered the Army Medical Service as an assistant surgeon in 1843, serving with the 51st Light Infantry throughout the Burmese war of 1852–53, and was on board the Hon. East India Company's steam frigate *Feroog* during the naval action and destruction of the enemy's stockades in the Rangoon river, also being actively employed during the succeeding three days' operations in the vicinity and at the storming and capture of Rangoon, and the storming of the White House Redout. He was also at the capture of Bassein, in various skirmishes at Prome, and in the advance on Meaday. For these services he received the Burmese medal with clasp for Pegu. Subsequently gazetted to the 18th Royal Irish Regiment, he served in the Crimea during the Eastern campaign from February, 1856 (when he was advanced to the rank of surgeon), to the fall of Sebastopol, receiving the Crimean medal with clasp for Sebastopol and the Turkish medal. Whilst in the same corps he acted as Principal Medical Officer to the Southern India Field Force in the Northern Mahratta country and the Deccan in 1857–58, and was subsequently selected as head of the medical branch in the Director-General's Office in London, afterwards proceeding to India as the chief administrative medical officer of the Sirhind circle in Bengal. On his return from India he was appointed head of the Army Medical Department in Ireland. Not long afterwards he returned to India as Surgeon-General of Madras, and subsequently as Surgeon-General and Principal Medical Officer of Her Majesty's forces in that empire. He occupied that position during the latter part of the second Afghan Campaign, and was thanked for his services in General Orders by the Commander-in-Chief and by the Governor-General in Council. From this responsible post he returned in 1882 to assume the duties of Director-General of the Army Medical Service, in succession to Sir William Muir, which office he filled till his retirement in May, 1889. Whilst serving as Principal Medical Officer in India, Surgeon-General Crawford was mainly instrumental in introducing the station hospital system into that country, by which a very large financial saving to the Indian Government was effected. Sir Thomas Crawford, who was created a K.C.B. in 1885, was, as we have already stated, an Hon. LL.D. of Edinburgh, an Hon. Fellow of the Royal College of Surgeons and of the Royal College of Physicians, Ireland, an M.Ch. of the Royal University of Ireland, and one of the honorary surgeons to

Digitized by Google

Her Majesty from October, 1886. He had also been a member of the Senate of the Army Medical School at Netley. The deceased officer was twice married; his first wife died in 1860, and in 1869 he married the daughter of the late General Edwards, C.B. Lady Crawford, who was a most amiable and charming woman, died in the spring of the present year, to the great grief of all who knew her, but especially of her husband and their children, to whom their loss was an irreparable one. Sir Thomas Crawford's death has soon followed that loss, and it may be safely affirmed that no more upright or energetic public servant was ever conveyed to the grave than was borne there on Tuesday last. Sir Thomas Crawford, whose health and strength had been sensibly declining since his wife's death, suffered of late from the effects of prostatic disease and cystitis, on which uræmic symptoms eventually supervened. He was buried at Charlton Cemetery on the 15th inst., where his predecessor in the direction of the department and his great friend, Sir William Muir, lies interred.

Our illustration is a reproduction from a photograph by Mr. Wayland of Blackheath and Streatham.

THOMAS KEITH, M.D., F.R.C.S. EDIN.

THOMAS KEITH was born in the village of St. Cyrus, in Kincardineshire, on May 20th, 1827. He was the youngest but one of seven sons, three besides himself adopting the medical profession. His father was the well-known Rev. Dr. Keith, the author of several works on prophecy, the most noted of which was written more than half a century before his death, which took place at the age of eighty-nine. Always a delicate boy, Thomas Keith suffered from the early loss of his mother, and ascribed much of his ill-health through life to the want of proper care when a child. Educated first at the parish school, then at the Grammar School of Aberdeen and the High School of Edinburgh, he spent three years at the Arts classes at Aberdeen University, and then three in Edinburgh, being able to count one of these Aberdeen years as one of those necessary for the Edinburgh medical curriculum. In 1845 he was apprenticed to Sir J. Y. Simpson, and in his second year was put into the Maternity Hospital as house physician. In 1848, at the age of twenty-one, he graduated M.D., and was taken by Mr. Syme as his house surgeon. After fifteen months, and when he had arranged to stay another year with Mr. Syme, the appointment of physician to the British Embassy at Turin was offered to and accepted by him, and he spent two years in Italy. Returning to Edinburgh he became partner with his brother, Dr. George Skene Keith, in one of the largest general practices in that city, and in addition gave considerable attention to diseases of the ear, and up to the date of his leaving Edinburgh did a considerable amount of aural work. But his desire was always towards surgery. There is a certain amount of romance almost connected with his first operation of ovariotomy. In 1862 a workman employed putting in some windows was much impressed with Dr. Keith's knowledge of glass, which he had gained in the early days of photography, and spoke to him about his wife, who had a tumour. Dr. Keith gave the man little encouragement at first, but yielding after a time he saw the patient, and in answer to the inquiry whether the tumour could be removed told her and the husband that the operation of ovariotomy was nearly always fatal, that he had never seen it performed, but that he was willing to try. The patient said that she was willing to run any risk, and the ovarian tumour was removed in 1862, the case being complicated by a rupture of the cyst and double pleurisy. The husband was kept up most of the night before the operation boiling the water which was to be used, and one large sponge was inserted into the peritoneal cavity once; but the opinion of those present was that this dangerous interference with the peritoneum, as it was then thought, must not be repeated. Nature made a drain for the retained fluid towards the end of the second week by making an opening through the lower part of the wound. In this, his first case, Dr. Keith laid the foundation of his success—chemical cleanliness was what he aimed at, cleanliness not so much of the surroundings as of the patient and of everything that was to come in contact with her, and he also saw the necessity of leaving the peritoneal cavity dry. His second case also recovered; the third he found dead in bed one morning and the nurse lying dead drunk on the floor; the fourth was the largest he ever removed, the tumour lying not only on the thighs, but on the legs of the patient. The operation was performed in a cottage in the country, and the weight of the tumour and fluid removed was 120 lb., in addition to which a large amount of fluid escaped on to the floor. When the patient was put back to bed apparently moribund Dr. Keith said to the nurse that she would not give her much trouble as she would die soon; some weeks later the woman had the pleasure of telling Dr. Keith what she had heard him say. These recoveries, with others which followed, made a great sensation, and Dr. Keith thus in conjunction with his friend Mr. (now Sir) Spencer Wells, who had begun his great work four years earlier, established on a firm footing the operation of ovariotomy in Great Britain and in a lesser degree over the whole world. It is mainly to these two men, friends for over thirty years, that abdominal surgery is in the position it is to-day, for they were instrumental in laying the foundation upon which all abdominal operations have been founded.

In 1864, after some months of almost constant vesical irritation and pain, during which Dr. Keith continued hard at work, Mr. Syme opened the bladder, but failing to find a calculus there he succeeded in removing one from the urethra. Within six weeks of being operated upon, and before the wound was healed, Dr. Keith with his wonderful energy performed a difficult operation in Dumfriesshire. In 1866 a visit to Koeberlé at Strasburg taught Dr. Keith the use of the spirit lamp for cleaning the points of all instruments. He also saw the catch forceps, at that time unknown in England, and brought home two of Koeberlé's drainage-tubes. These were seen to be too short, and it was evident to Dr. Keith that the drainage must be from the bottom of the pelvis. Until Dr. Keith commenced to use the carbolic spray in 1887 all his instruments were put through the flame of a spirit lamp, thus realising very much the idea of chemical cleanliness. His dressing for years for all wounds had been gauze or lint soaked in carbolic and glycerine. About 1866 Dr. Keith was asked to become surgeon for ovarian diseases to the Royal Infirmary. Unfortunately, the only room available was one in the medical house close to the small-pox and scarlet fever wards, and he therefore preferred to open a small private hospital, in which he operated on any poor woman who was sent to him either from the hospital or elsewhere, lodging, feeding, nursing, and sometimes burying, them at his own expense. When the new infirmary was opened in 1879 suitable, though inadequate, accommodation was found for him, and on one occasion as many as eighty patients were on the list waiting for admission. In 1885 his son, who for some time had unofficially been doing most of the work, was associated with him. Until the spray was used Dr. Keith's health had been improving, and for some years he had had no hæmorrhage from the kidneys; but the poison was too much for these organs damaged by the presence of cystine calculi for many years, and at first after long operations, and then after most, there was a return of these attacks of hæmaturia. The spray was not discarded, however, until patients began to suffer in the same way. Since then he returned very much to his old practice; every instrument was washed as carefully as formerly, but instead of the spirit lamp carbolic acid was used, the skin of the patient and everything that came in contact therewith was carefully disinfected, although the elaborate washing of hands and disinfecting of rooms was looked upon by him as unnecessary. As an example of his great success it may be mentioned that one day the undertaker who was employed when a death occurred in his private hospital stopped the nurse in the street and asked her if he had offended the doctor, explaining that he had had no work from him for such a long time.

In 1871 a portrait of Dr. Keith, along with a service of plate, was presented to Mrs. Keith. In making the presentation Professor Christison said: "There were several grounds which had led to this expression of admiration—viz., Dr. Keith's great success in treating one of the most terrible diseases which may affect the life of women, his disinterestedness, his fine character, his devotion to duty, and the appreciation of the great sacrifice he had made in pursuit of his object. The great operation which Dr. Keith had so often and so successfully performed had been at one time looked upon as almost certainly fatal, and had been kept from disuse by one or two bold surgeons until the time when Dr. Keith and another

Digitized by Google

surgeon in the South had succeeded in establishing it as one of the legitimate operations in surgery." Ovariotomy led to other operations, and hysterectomy in his hands became almost as safe; but he never liked the operation, and condemned in no measured terms the number of such operations which are now performed. It was with keen interest that he watched the progress of Dr. Apostoli's treatment. In 1887 one of his sons went to Paris to learn the new method from Dr. Apostoli, and on his return Dr. Keith decided that no operation should be performed for fibroid tumours of the uterus until electricity had been fairly tried on a number of cases. Over one hundred tumours were thus treated, and the results on the whole were so good that Dr. Keith did not perform many operations for fibroid tumours of the uterus after that time, though, strangely enough, the last operation but one performed by Dr. Keith, now nearly three years ago, was a hysterectomy, his last being a fixing up of the uterus by his operation of clamping the broad ligament. In 1888 Dr. Keith left Edinburgh for London; he had missed greatly his old friends, the late Dr. Mathews Duncan and Sir Joseph Lister. In 1889 he paid a professional visit to Mexico, his second to the new world. On the 9th inst. Dr. Keith quietly passed away, after a life of uncomplaining suffering and ill-health, of which few knew, but none better than his life-long friend, Dr. Mathews Duncan, who, in a dedication, has described him as a "hero in surgery."

Dr. Keith is survived by his widow, four sons, and three daughters. Two of the sons are medical men.

JOHN WATERS, M.R.C.S. ENG.

THE death on Tuesday, the 8th inst., at the age of sixty-seven years, of Mr. John Waters, of 41, Bloomsbury-square, W.C., has been a source of deep regret to all his friends. His illness had lasted nearly eighteen months and was borne with exemplary patience. Having completed his professional education as a student of the Middlesex Hospital, he obtained the diploma of the Royal College of Surgeons of England in 1856. He subsequently became a Fellow of the Medical Society of London and was for some years one of the surgeons to the Farringdon Dispensary. Up to within a few weeks of his death he discharged with untiring zeal and energy the duties appertaining to his official capacity as a member of the various governing boards of the parishes of St. Giles and St. George, Bloomsbury. To a thoroughly practical knowledge of his profession he added a geniality of manner which procured for him the esteem and affection, not only of his patients, but also of a large circle of friends.

ALFRED JOHN WILLIAMS, M.R.C.S. ENG., L.R.C.P. LOND.

WE regret to announce the death, at the early age of thirty-two years, of Mr. Alfred John Williams, recently in private practice at West Hill, Wandsworth. Mr. Williams received his medical training at King's College Hospital, which he entered in 1884. He was house surgeon to Professor Cheyne whilst Professor Koch's treatment by means of tuberculin was being carried out in Professor Cheyne's ward. In his observation of the treatment he displayed great earnestness and ability, subsequently contributing the result of his studies to our columns under the heading "Notes on Tubercular Cases under Koch's Treatment in King's College Hospital." He afterwards became a surgeon on board one of the P. and O. Company's steamers. After two years in this post he settled down at Wandsworth, where, as parish medical officer during the eighteen months previous to his decease, he won the esteem of all classes for his devotion to the poor. He was attacked by typhoid fever whilst in the discharge of his duty, and died in the third week of his illness. At King's College Hospital Mr. Williams was well known for his devotion to duty, while his good-nature endeared him to all his contemporaries.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Jos. Oettinger, formerly Professor of the History of Medicine in the University of Cracow.—Dr. V. J. Eltsinski, formerly Professor of Special Pathology in Moscow, at the age of sixty-two.

Medical News.

UNIVERSITY OF GLASGOW.—The following have passed the First Professional Examination (New Regulations) for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch. B.) in the subject or subjects indicated after their respective names (B., Botany; Z., Zoology; P., Physics; C., Chemistry):—

George Alexander (B., C.), Andrew Aitken Barclay (B., Z.), James Freeborn Bennett (B., P.), Andrew Brownlie (B., Z., C.), George Frederick Buchan (P.), James Carruthers, M.A., (C.), George Morris Crawford (Z.), Charles Peter Garvie Crichton (B., Z.), Charles Cheven Cumming (B., C.), William Dick (B., P.), James Austin Dickie (B., C.), Frank Lindsay Dickson (B., P.), David Curr Douglas (B., Z.), John Pinkerton Duncan (B., C.), Hugh Campbell Ferguson (Z., C.), Comyn MacGregor Finlay (B.), John Andrew Garden (Z., C.), George Gardner (B., Z., C.), John Gardner (Z., P.), George Garry (Z., C.), William Gibson (Z., C.), Hyam Goodman, M.A. (B., Z., C.), Charles Aikman Gourlay (Z.), Nicol Jamieson (Z., P.), Andrew Kerr (C.), John Francis Lambie (B.), Norman Maclean Leys (B., P.), Andrew Love (Z., C.), Ramsay Millar (B., C.), Ebenezer Mitchell, M.A., (Z., C.), Daniel Morrison (Z., C.), Peter MacIntosh M'Fadyen (B., C.), John M'Gilchrist (B., C.), Charles Forbes Maclean (B.), George Todd Maclean, M.A. (B., Z.), Norman Forbes Macleod (B.), William Johnston Maclure (Z., C.), John M'Millan (Z.), Wm. Seymour MacMillan, M.A. (B., Z., C.), John Patton (P.), Thomas Stephens Picken (B., C.), John Reid, Lanark (P., C.), David James Smith (B., C.), John Steele Smith (Z., P.), William Stewart Stalker (B., Z.), Peter Alexander Steven (Z., P.), Alfred George Stewart (B., P.), Thomas Morton Straug (P., C.), Robert Taylor (Z., C.), Charles Pinkerton Thomson (B., P.), William Brown Thomson (Z., C.), Joseph Swinburne Townley (P., C.), John Turnbull (B., Z.), Arthur Vost (B., Z., P.), Alexander Laurie Watson, M.A. (B., C.), Joseph White (Z., C.), Morgan Watkin Williams (B., C.), Alexander Wilson (B., C.), William Wright (B., C.), John Doctor Young (B., P.).—Women candidates: Marjorie King Henderson Fleming (B., Z.), Helen Mary Gordon (B., Z.), Mabel Hardie (B., Z.), Catherine Spence Howden (B., Z.), Jessie Sophia Beatrix Hunter (B., Z.), Ina Lochhead M'Neill (B., Z.), Maud Ada Richards (B., Z.), Elizabeth Helen Smith (B., Z.), Edythe Marjorie Walker (P., C.).

The following have passed the First Professional Examination (Old Regulations) for the degrees of Bachelor of Medicine (M.B.) and Master in Surgery (C.M.):—

Stewart Dunbar, George Munro MacLeod.—Women candidates: Martha Jane Gilmore Cox.

The following have passed the Second Professional Examination (New Regulations) for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.) in the subject or subjects indicated after their respective names (A., Anatomy; P., Physiology; M.M. and T., Materia Medica and Therapeutics):—

Alexander Smith Allan (M.M. and T.), James Alston (A., P., M.M. and T.), George MacLellan Blair (M.M. and T.), John George Wilson Boleyn (A., P.), William Cochran Burns (A., P.), David Louis Cairns (M.M. and T.), Francis James Charteris (M.M. and T.), George Clark (A., P., M.M. and T.), Joseph Adam Clarke (M.M. and T.), George Coats (A., P., M.M. and T.), George William Coats (M.M. and T.), James Duncan Cochran (M.M. and T.), Joseph Muir Corbett (A., P., M M. and T.), Robert Crawford (A., P.), John Crow (A., P.), Walter Scobie Findlay, M.A. (M.M. and T.), James Finlayson Fleming (M.M. and T.), Adrian Andrew Forrester (M.M. and T.), Thomas Bonnar Garvie (A., P., M.M. and T.), Thomas Hunter, M.A. (A., P.), Alexander Lawrie (P., M.M. and T.), Alexander Millar Lindsay (A., P.), John Watson Little (A., P., M.M. and T.), John MacDonald (M.M. and T.), Murdoch Macdonald (A., P.), James M'Haffie (M.M. and T.), David M'Kail (M.M. and T.), Laurence Abel Mackenzie (A., P., M.M. and T.), James M'Queen, M.A. (M.M. and T.), James Service Ormond (A., P., MM. and T.), John Reid, Glasgow (A., P., M.M. and T.), Norman Emil Henry Scott (M.M. and T.), Robert Scott (A., P.), John Laird Simpson (A., P.), Alexander Bankier Sloan (M.M. and T.), Samuel Macfarlane Sloan (M.M. and T.), David Steele Smith (M.M. and T.), John M'Callum Stewart (A., P., M.M. and T.), Donald Sage Sutherland (A., P., M.M. and T.), James Douglas Carnon Swan (A., P.), Matthew Logan Taylor (M.M. and T.), Daniel Rees Thomas (A., M.M. and T.), Walter Lewis Thomson (M.M. and T.), William James Alexander Walker (A., P.), William Watson (M.M. and T.), John Wotherspoon (A., P.), William Wyper (M.M. and T.), David John Young (M.M. and T.)—Women candidates: Daisy Annabelle Bennett (A.), Mary Gardner (A., P.), Jane Lorimer (A., P.), Minna Amelia Macfarlane (A., P.), Agnes Renton Robson (A., P.), Catherine Love Smith A., P.), Jessie Hawkesworth Smith (M.M. and T.).

The following have passed the Second Professional Examination (Old Regulations) for the degrees of Bachelor of Medicine (M.B.) and Master in Surgery (C.M.):—

Andrew Phillips Aitken, Walter Colquhoun, M.A., William Duncan, Charles Elphinstone Fleming, James Millar, James Rankin, B.Sc., Alexander Page Robertson, David Wallace Smith, Alex. James Thompson Swann.—Women candidates: May M'Mullen Pearson.

The following have passed the Third Professional Examination for the degrees of Bachelor of Medicine (M.B.) and Master in Surgery (C.M.):—

(*A*) *Including Pathology.*—William Allen, James Mitchell Bonar, Hugh Borland, William Brown, James Butler, Hugh Calderwood,

Digitized by Google

B.Sc., John Lindley Carstairs, M.A., Thomas Cochrane, Peter Latimer Leitch Craig, M.A., James Gardner, William Hansen, John Hepburn Lyell, Archibald Mason, Andrew Brown Murray, Norman Macnair, B.Sc., Robert Nelson, William Seaton Paterson, David Lyon Stevenson, M.A., Henry Hyslop Thomson, Andrew Colville Wilson, B.Sc.—Women candidates: Agnes Jane Anderson, Mary Philip Graham, and Mildred Ransome.

(*B*) *Not including Pathology.*—Donald M'Gregor Campbell, John Arthur Clarke Doonan, John Sharp Douglas, Charles Lowson, William Martin, M.A., John Irvine MacMillan, M.A., William M'Mullen Pearson, James Hood Rankin, James Rutherford Ratcliffe, Alexander Robertson, and John Taylor.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.—The following gentlemen passed the Second Examination of the Board in the subjects indicated on Wednesday, Oct. 9th:—

Anatomy and Physiology.—Laurence Otway Fuller, Edward Augustus Bullmore, Walter Sirr Sheldon, and Arthur Edward Francis, University College, London; Nelson Joseph Roche and Victor Stanley Partridge, Charing-cross Hospital; Charles Louis Francia, Bernard Edward Granville Bailey, Edmund Newton Berryman, Alexander Hampton Brewer, and John Kenneth Sprot Fleming, St. Bartholomew's Hospital; William Reginald Cazenove, Harold Percy Waller Barrow, Jenkins Howells, and Norman Williams, Guy's Hospital; Frank Bawtree, St. Thomas's Hospital; Warren Meade, St. George's Hospital; Harry Hipwell, Middlesex Hospital; and Kenneth de Risley Bell and Henri Nelson Harness, King's College, London.

Anatomy only.—Henry Priest Shanks, University College, London; and Edgar Curnow Plummer, King's College, London.

Sixteen gentlemen were referred in both subjects, and one in Anatomy only.

Thursday, Oct. 10th:—

Anatomy and Physiology.—George Gunning Campbell, Edward Percy Court, William Henry Cazaly, John Dalebrook, and Norman Humbert Joy, St. Bartholomew's Hospital; Peter Rowley Tarbet and David Llewelyn Kurtz Pritchard, University College, London; Arthur Daniel Lewis, Hugh Watson Fox, and William Walter Harrison, Guy's Hospital; Harold Cotterell Adams, Middlesex Hospital; James Charles Stewart Oxley, St. Thomas's Hospital; John Ignatius Worgan Morris and Llewellyn Lindop, St. Mary's Hospital; Ralph Bignell Ainsworth and Francis Barrallier Thompson, St. George's Hospital; and Fritz John Alfred Beringer, London Hospital.

Anatomy only.—Arthur Wellesley Penrose, Guy's Hospital; Arthur Cyril Bird, St. Thomas's Hospital and Mr. Cooke's School of Anatomy and Physiology; Walter Amsden, St. Bartholomew's Hospital and Mr. Cooke's School of Anatomy and Physiology; Frank Howard Lawson and Edward Simpson Shave, Middlesex Hospital; and Ernest John Distin and John James Cecil Hamilton, King's College, London.

Physiology only.—George Herbert Doming, St. Thomas's Hospital; and Colville Smith Agnew, Charing-cross Hospital.

Twelve gentlemen were referred in both subjects, one in Anatomy only, and one in Physiology only.

FOREIGN UNIVERSITY INTELLIGENCE.—*Bahia:* Dr. José Carneiro de Campos has been appointed Professor of Anatomy.—*Buda-pest:* Dr. Julius Elischer, Lecturer on Gynæcology, has been granted the title of Professor.—*Cracow:* Dr. Jakubowski has been promoted to the Ordinary Professorship of Children's Diseases.—*Innsbruck:* Dr. Dimmer of Vienna has been appointed to the chair of Ophthalmology.—*Munich:* Dr. Otto Frank has been recognised as *privat-docent* in Physiology, Dr. H. Neumayer as *privat-docent* in Laryngology, and Dr. Martin Hahn as *privat-docent* in Hygiene.—*Prague (Bohemian University):* Dr. F. Marés has been promoted to an Ordinary Professorship of Physiology.—*Rostock:* Dr. Schuchardt has been appointed to the newly established Professorship of Psychiatrics.

THE TENTH ANNIVERSARY OF THE INTRODUCTION OF THE "SAFETY" BICYCLE.—In an annotation in the last issue of THE LANCET on "The Dangers of Cycling" mention was made of the introduction of a machine in 1885 which has served as the model upon which the most popular machines have since been constructed. The name of this machine, which was omitted by an inadvertence, is the "Rover," and a dinner in commemoration of the tenth anniversary of its introduction was recently given by its inventor, Mr. J. K. Starley, at the Café Royal, Regent-street, W.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—The following Entrance Scholarships have been awarded:—In Arts, an Entrance Scholarship of £145 to Mr. Thomas Crisp English, and Entrance Scholarships of £50 to Mr. Henry Ayrton Chaplin, Mr. Lidbrooke Frank Cope, and Mr. Lawrence Jones. In Science, Entrance Scholarships of £85 to Mr. Herbert Stringfellow Pendlebury, B.A., Pembroke College, Cambridge; to Mr. Henry Goodridge Deller, B.A., Trinity College, Cambridge; and to Mr. John Howell Evans, B.A., non-collegiate student of Oxford. The two last named were bracketed, but owing to the excellence of their papers a full scholarship was awarded to each.

KING'S COLLEGE, LONDON.—Entrance scholarships have been awarded at this College to the following gentlemen—viz., to Mr. R. N. Batterbury, a Warneford scholarship of the value of £25 for three years, and to Messrs. J. G. Pritchard and H. G. Wright similar scholarships for two years each. The Clothworkers' Exhibitions have been awarded to Mr. C. F. Mott (£30 for two years) and Messrs. R. H. C. Gompertz and C. L. Cartwright (£20 for two years). The Sambroke Exhibitions have been awarded to Mr. W. L. Stuart (£60) and A. C. Williams (£40).

THE WATER QUESTION AT GODALMING.—The corporation of the borough of Godalming has decided in favour of public as against private water-supply, and intends to purchase the undertaking of the local water company. The value of the works is put at £33,267 and the price asked is £37,500; mortgage debentures, transfer costs, and additional necessary storage works will run the total figure up, it is estimated, to £48,000. It is proposed to borrow this sum, with interest payable during the first five years, and capital and interest by equal instalments during the succeeding fifty-five years, a sixty years' loan in all. The same evening the corporation agreed to apply for a provisional order to light the borough by electricity.

THE DIFFUSION OF SMALL-POX.—The information reaching us concerning the prevalence of small-pox during the first fortnight of the present month shows continued diminution of the disease in the provinces as well as in London. In the metropolis the last three weeks of September had shown cases to the number of 42, 23, and 21 respectively as having been removed to hospitals of the Metropolitan Asylums Board or to the Highgate Small-pox Hospital, wherein the cases remaining under treatment in the same weeks had fallen from 307 to 234; whilst in the opening week of October the new attacks removed numbered only 17, and the patients under isolation had fallen still further to a total of 198. There was one registered death, the deceased belonging to the Wandsworth sanitary area and being an unvaccinated infant under the age of twelve months. Last week the decline continued, only 9 cases occurring, and the hospitals housing on Saturday, Oct. 12th, only 153 patients suffering from small-pox—a total considerably less than half that which obtained at the close of August. There were two registered deaths, occurring in unvaccinated children belonging to as many sanitary areas in East London. Whilst, therefore, we can congratulate ourselves on a falling record of small-pox occurrences in the metropolis, it is well to remember that the period of autumnal recrudescence is upon us, and that action of a preventive character cannot with prudence be relaxed in view simply of a present quiescence of the malady. In the home counties small-pox has apparently disappeared for the present, and in the midland counties attacks are solitary in their occurrence, the few cases cropping up westward being scattered, and the northern districts east of Lancashire having a free bill of health in this respect. There has, however, been a serious outbreak in the Wigan district. At Aspull it has been so widespread that the schools have been closed for an indefinite period, and it is reported that a large number of persons have been removed to the sanatorium. On Tuesday of last week it was ascertained that 14 persons had been removed from Aspull to the institution, and that, including cases from the borough of Wigan, there were over 20 patients in the hospital suffering from small-pox. In the city of Manchester there have been upwards of a score of attacks since the beginning of September, the district of Openshaw being chiefly in question, though cases have also arisen in Newton Heath and Beswick localities of the city. The adjacent borough of Salford, nevertheless, continues free from the disease. In Oldham much more favourable accounts are to hand, for whereas in the fortnight ended Sept. 21st there were 11 new cases, there was not 1 recorded in the succeeding fortnight, 1 death, however, being registered. The last week of September and the initial week of October have not been so fortunate for Dublin in the matter of small-pox as earlier recent weeks, for in the last week of the month there were 2 deaths registered, both in vaccinated adults aged over twenty years; and whilst only 2 new cases were admitted to hospital, leaving 18 under treatment at the close of the month, the next week witnessed 11 fresh admissions, with another death in a vaccinated adult; and the hospital roll showed 27 patients as being under isolation on Oct. 5th.

THE committee of the Bethnal Green Free Library have received from Mr. Charles Welch, F.S.A. (librarian at the Guildhall), and his brother, Mr. S. Welch, M.R.C.S., the gift of the library of their late father, Mr. Charles Welch of Hackney-road, who was for more than forty years the friend of the poor of Bethnal-green and medical officer of the district, and who always took a warm interest in the progress of the institution. In order to provide new shelving and bookcases for this and other gifts to the library and pay for cataloguing about £100 will be required, and the committee will be deeply grateful for any contributions, which should be sent to Mr. G. F. Hilcken at the Library, London-street, E.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—At the quarterly court of the directors held on Oct. 9th, the President, Sir James Paget, being in the chair, two new members were elected. There were no fresh applications for grants. Applications for continued assistance were read from 51 widows, 8 orphans, and 4 orphans on the Copeland Fund, and it was determined that a sum of £1182 10*s.* should be distributed at the next court subject to the report of the visitors. A sum of £452 was voted to be given at Christmas—viz., £8 each to the 51 widows, £3 each to the orphans, and £5 each to the 4 orphans on the Copeland Fund. A grant of £20 towards the self-maintenance of an orphan was made, and a special grant of 10 guineas was given to a widow. The expenses of the quarter amounted to £55 9*s.*

ÆSCULAPIUS LODGE.—The installation meeting was held at the Café Royal, Regent-street, on Wednesday, the 9th inst., when G. Crawford Thomson, M.D., was installed Master for the ensuing year. W. Anthony Nutt was appointed Senior Warden, G. Danford Thomas, M.D., Junior Warden, J. Pickett, M.D., Treasurer, and Thomas Dutton, M.D., Secretary. T. Horrocks Openshaw, M.B., M.S. Dunelm., F.R.C.S. Eng., was elected a joining member. Messrs. William Harrison, M.A. Cantab., and R. T. Hacker Bodilly, L.R.C.P. Lond., M.R.C.S. Eng., were admitted members. A cordial vote of thanks was recorded to Lennox Browne, F.R.C.S. Edin., G. Danford Thomas, M.D., and Thomas Dutton, M.D., for the very able manner in which they had carried out the work of the smoking concert which the lodge and chapter gave to the provincial medical Masons during the meeting of the British Medical Association in London last August. After the transaction of other routine business the lodge was closed and the brethren adjourned to the banqueting room, where they entertained visitors who had honoured the lodge with their company. A most enjoyable social evening was spent.

BEQUESTS TO HOSPITALS.—Mrs. Mary Ash, late of Victoria-square, Bristol, has bequeathed £200 each to the following Bristol medical charities—namely, the Royal Infirmary, the General Hospital, the Children's Hospital, the Medical Mission, and the Clifton Dispensary.—The late Mr. Alfred Lee of Mount Hermon, Woking, has bequeathed £500 free of duty to the Surrey County Hospital.—The managing committee of the Wolverhampton Eye Infirmary has received from the executors of the late Mr. John Parkes £250.—The late Mr. John Hughes of Wynnstay, Sefton Park, Liverpool, has bequeathed £350 to the Liverpool Blue Coat Hospital, £300 to the Liverpool Eye and Ear Infirmary, £200 each to the Liverpool Royal Infirmary and the Royal Southern Hospital, and £100 to the Stanley Hospital.—Miss Frances B. Fetherstonhaugh, late of Up Park, Sussex, has bequeathed £500 to the Chichester Infirmary.—The late Mr. Bernard V. Hall of Liverpool has bequeathed £5000 to the Liverpool Royal Infirmary, £2500 each to the Liverpool Royal Southern Hospital and the Liverpool Royal Northern Hospital, and £1000 to the Ladies' Charity and Lying-in Hospital.—Mr. Henry Nathan, late of Pembroke-gardens, London, has bequeathed £100 to the Jewish Hospital and Orphan Asylum, Lower Norwood, £50 each to the Metropolitan Free Hospital, Gray's Inn-road, the London Hospital, and the German Hospital, Dalston, and £100 each to the Birmingham General Hospital, the Birmingham Children's Hospital, and the Birmingham Queen's Hospital.—The late Mr. William Woolfall of Liverpool and New Brighton has by his will left the following legacies: Liverpool Royal Infirmary, £2000; Northern Hospital, £500; Royal Southern Hospital, £500; Stanley Hospital, £200; Wallasey Cottage Hospital, £100; Wallasey Dispensary, £100; Liverpool Hospital for Consumption, £100; Liverpool Dispensaries, £200; Liverpool Dental Hospital, £100; Liverpool Hospital for Cancer &c., £100; Liverpool Eye and Ear Infirmary, £100; and the Liverpool Infirmary for Children, £100.

Notes, Short Comments, and Answers to Correspondents.

EDITORIAL NOTICE.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

"APPOINTMENT OF HOUSE SURGEON TO THE NORTH CAMBS HOSPITAL, WISBECH."

To the Editors of THE LANCET.

SIRS,—As the letter in THE LANCET of Oct 5th from "J. S. B., D. S., and R. E." may leave your readers under an erroneous impression, I should be obliged if you would allow me to state the facts of the case, with which those gentlemen were not acquainted. For the post of house surgeon there were eighteen candidates, *of whom Dr. Taylor was one.* He and the other seventeen sent in testimonials, all of which, I may say, were of very high character. From the eighteen candidates, after careful consideration, were selected *four, of whom Dr. Taylor was one.* He was acting as locum-tenent for the retiring house surgeon, and was informed verbally. Our honorary secretary, in writing to the other three, by a clerical error which we all regret, mentioned *three* as the number selected. In summoning the members of the committee to the special meeting he mentioned *four.* At this meeting each of these four gentlemen was invited in turn to interview the committee. After these interviews and some discussion the matter was put to the vote. Of the nineteen members of the committee twelve voted for Dr. Taylor, who was accordingly elected.

I am, Sirs, your obedient servant,

Wisbech, Oct. 10th, 1895. ROBERT R. R. WATTS, Chairman.

PERSISTENT HICCOUGH AND SNEEZING: A SUGGESTION WANTED.

To the Editors of THE LANCET.

SIRS,—A patient (female) aged twenty years has now been under treatment for a couple of years for the cure of hiccough and sneezing. Not a single day passes without her suffering from an attack, which very often continues from four to five hours, and leaves her in a very collapsed condition. She is a nervous patient, but not particularly so. Her dietary is a good one, and she takes a fair amount of open-air exercise, and lives in a good social sphere. There is no organic lesion in the throat or nose to give rise to any local irritation. Her powers of digestion are good. All the usual remedies, both local and constitutional, have been tried, but of no avail. Perhaps some of your readers would kindly suggest a means of treatment.

I am, Sirs, yours faithfully,

Glasgow, Oct. 13th, 1895. R. H. ALLEN, M.B., C.M.

"PASSING RICH WITH FORTY POUNDS A YEAR."

WE have had brought to our notice the following advertisement, which has appeared in the *Galloway Advertiser and Wigtownshire Free Press*, and we confess to being deeply puzzled by it.

> "WANTED.—MEDICAL OFFICER (Resident) and Vaccinator for the Parish of Portpatrick. Salary, including medicines, £40 per annum; to attend private patients at the scale of fees fixed by Parish Council, copy of which can be obtained from the clerk. To enter upon duties on 11th November. Canvassing a disqualification.—Applications, with testimonials, to be lodged with the clerk of the Parish Council, Portpatrick, not later than 25th October."

The salary offered to the medical officer and public vaccinator of the parish is not large if it is to be his only source of income, for even the most frugal of Scotchmen would find it difficult to emulate the village preacher of "Sweet Auburn," and be passing rich with £40 a year. Naturally the medical officer will desire to have as large a private practice as he can get, and his official salary has been fixed from that point of view; but the parish council, it will be seen, propose to fix the scale of fees at which he shall attend private patients. This is, indeed, a departure, and one which will, we hope, make it very difficult for the parish council to obtain an officer. For, firstly, no one can fix the fees properly at which another man should attend private patients. This is entirely a matter for mutual arrangement between patient and attendants, and the interference of the parish council must lead to injustice to someone. And, secondly, the position assumed by the parish council towards their officer is intolerable. If they exercise the prerogative indicated in their advertisement they would have him entirely at their mercy; they could make his fees so high that no one at Portpatrick would employ him, or so low that he could not earn a living wage. We are sure that the council have not quite understood the nature of the new duties they propose to take upon themselves.

Hibernicus.—All the information our correspondent seeks can be obtained from the agents of the various lines, most of whose addresses can be found in the London, Liverpool, or Glasgow Directories.

M.D. is thanked for his communication. It is wrong that medical men should be expected to give certificates gratuitously. They should be paid for by those in whose interests they are demanded.

Riparian.—The cost can be made anything. Our correspondent is recommended to write to the four different Inns for information.

RIGOR MORTIS IN THE FŒTUS IN UTERO.

To the Editors of THE LANCET.

SIRS,—Some few years ago I sent an account to a contemporary of a case in which rigor mortis in the fœtus in utero was the cause of difficult labour. During the last two years I have had three other cases, so that an event which I looked upon as rare must not infrequently occur; but it appears to have passed unnoticed by the generality of practitioners, as everyone to whom I have spoken about the matter has confessed that he had never even heard of, much less seen, such a case, and the text-books do not mention it. The following notes of my last case are, I think, worth placing upon record.

On Sept. 6th I was called in to a primipara aged thirty-seven by the midwife in attendance, as, though the os was fully dilated, no advance of the head had taken place for several hours. On applying forceps considerable resistance was experienced, and what I expected to find an easy forceps case proved to be quite the reverse. Progress was slow until I secured extension, when the head came down well; but further difficulty was experienced in extracting the body, which gave the impression of being much too large for the maternal passages. The fœtus, however, proved to be not large, but rather under the average. The difficulty had arisen at the various stages: first, the normal flexion had not taken place, and at a later stage the stiffness of the neck had prevented extension, and the lateral flexion of the body had been interfered with owing to the same cause. Rigor mortis was well developed all over the body, the arms and legs being stiff and in the flexed position. On balancing the child's body on one hand its back kept almost straight and the legs in the same flexed position, the heels not dropping below the nates. Owing to the forcible flexion of the neck the head moved upon the trunk like a hinge joint. At the moment of applying pressure with the forceps there was a crunching noise quite audible, sounding as if one were breaking a bone.

I am, Sirs, yours faithfully,

B. JONES, M.D. Durh., M.R.C.S., &c.

Leigh, Lancashire, Oct. 5th, 1895.

Squills.—The person who has been left a legacy or share of residue in a will should not be an attesting witness to the execution. The attestation would be good, but the legacy would be forfeited. An executor may be a legatee under a will and very generally is. Our correspondent does not explain his position very clearly, and if these are not the only two points upon which he desires advice he had better consult a solicitor.

IMAGINATION AGAIN.

AT a recent inquest in the Shoreditch Coroner's Court a lay reporter made the medical man who had made the post-mortem examination of the body say that he had found death to be due to the deceased's heart having "burst in half," and that the only reasons to be assigned for the catastrophe were "over-excitement and eating too heavy a supper," and the paragraph was headed with a jocularity not quite apt to the occasion, "Death from a Broken Heart." The medical man, to whose attention the extraordinary statement credited to him has been brought, writes us the following account of the case, from which it will be seen that the "bursting in half" was a piece of reportorial exuberance:—

> "I was called on the Monday at 11.5 P.M., and found deceased just as she had fallen, in a crouching position on the floor, with her back against the bed, quite dead, and not resting in a chair as reported. I made a post-mortem examination on Thursday afternoon. I found the body well nourished and containing a fair amount of subcutaneous fat. The abdomen was greatly distended by air. The lungs were both gorged with blood, especially the right one—no doubt the beginning of an attack of congestion of the lungs. On opening the pericardium I found it completely distended with dark blood-clot and serum. The heart itself was soft and flabby, and presented the appearance of fatty degeneration; the valves were quite healthy, but the walls were thinner than normal. This was especially marked in the walls of the auricles, being very thin and soft. At the right side of the right auricle I noticed a patch a little larger than a shilling, and much deeper in colour than the surrounding tissue, presenting the appearance of recent inflammatory changes; at this spot there was an opening, with rugged edges, communicating with the interior of the right auricular chamber, and from which the hæmorrhage took place. The liver was larger than normal, soft, and friable; the kidneys were somewhat congested; the brain was normal, and the spleen also. I gave it as my opinion that the exciting cause of the rupture of the auricle was the hearty meal of eels and potatoes partaken of by the deceased, causing dyspepsia and flatulency, from which she often suffered, producing laboured action of the heart from pressure of an over-distended stomach, thus increasing the blood pressure from the stasis in the lungs, resulting in rupture, syncope, and death. I said nothing about over-excitement and I certainly never spoke of the heart bursting in half."

Mr. William Paul.—We agree with our correspondent that the subject is always deeply interesting; but we consider that the danger is practically non-existent, and that no immediate legal interference is necessary.

Messrs. Arthur and Co., of 69, Berners-street, Oxford-street, write, with reference to our notice last week (p. 921) of "Tannopumiline," that they have altered the name to *Tannopumilio*.

Mr. A. C. Elmore.—The story our correspondent tells us is not a creditable one.

"DROWNING FOLK-LORE."

To the Editors of THE LANCET.

SIRS,—The belief that men and women take a different position when floating after drowning is discussed by Sir Thomas Browne in the sixth chapter of the fourth book on "Vulgar Errors." The belief in his time dated from Pliny, and was that women floated face downwards and men on their backs. He says that Scaliger declines to accept the explanation that nature seeks to conceal thus the shame of the dead, preferring to attribute it to the fact that women take the prone position on account of the weight of the abdomen. "If so," says Sir Thomas Browne, "only men with great bellies will float downward, and only Callipygæ and women largely composed behind upward." If there is any truth in the fact that women float on their backs, it might be explained by the same reason as the floating of witches when put to the test of water—i.e., hysterical paralysis of the abdomen due to fright, and consequent gaseous distension of the intestine, which could not possibly assume the lower level in the water.—I am, Sirs, yours truly,

Oct. 12th, 1895. HISTORICUS.

Medical Jurist.—Our correspondent presents us with an excellent opening for casuistry. It is generally considered that when the cause of death is asked for it is the immediate cause that is meant, so that any cause directly behind that immediate cause should also be mentioned as primary. The primary cause in the example mentioned was the operation and the secondary cause the septicæmia. It is quite true that no operation would have taken place had there not been a pathological condition present, but such a train of reasoning can be reduced to absurdity. Suppose, for instance, the operation had been necessitated by a broken leg and the broken leg had been the result of a train accident—"locomotive attacks ye," as *Punch* has it—what would have been the primary cause of death?—the train, or the man who made it, or the driver, or George Stephenson?

A Constant Reader.—The regular and simple way of notifying a change of address is by sending to actual patients a visiting card with the new address substituted for the old one.

"A FEMALE MEMBER OF THE ARMY MEDICAL STAFF."

To the Editors of THE LANCET.

SIRS,—In the last issue of THE LANCET inquiry was made by a medical gentleman in the United States as to the facts of the services in the Army Medical Department of "James Barry," who, on her sudden death in Craven-street, Strand, was discovered at the inquest to be a woman.

In 1857 I travelled with this remarkable character on board the intercolonial steamer plying between St. Thomas and Barbadoes, when I occupied the same cabin, I in the top and she in the lower berth—of course, without any suspicion of her sex on my part. I well remember how, in harsh and peevish voice, she ordered me out of the cabin—blow high, blow low—while she dressed in the morning. "Now then, youngster, clear out of my cabin while I dress," she would say. A goat was on board to provide her with milk; she was a strict vegetarian, and she was accompanied by a negro servant and a little dog called "Psyche." The doctor was going at the time to visit her old friend and enemy, General Sir Josiah Cleote (commanding troops), with whom, when aide-de-camp to the Governor of the Cape, she had fought a duel and was wounded in the leg. The late Colonel Shadwell Clerke, who was at that period on the General's Staff, told me before his death last year that he, too, was challenged for some fancied insult, but that General Cleote pooh-poohed the idea and made them shake hands.

In person "James Barry" was short in stature, angular in figure, with a long Ciceronian nose, prominent cheek-bones, and a rather lugubrious expression of countenance. I possess a photograph of her, and there is another, kept under lock and key, in the medical officers' mess at the Royal Victoria Hospital here. Neither is a good likeness. Details of her life were given shortly after her death in the May number of *All the Year Round*, entitled "A Mystery Still," and from these particulars, as well as from such information as I subsequently gleaned, I formulated the heroine of my novel (in three volumes), "A Modern Sphinx," published in 1881, a reproduction of which in single volume, re-named and edited by Miss Braddon, "Madeline's Mystery," may still, I fancy, be obtained. "A Modern Sphinx" is out of print; but as I retain a few copies I shall have pleasure in placing a copy at your disposal for transmission, if you like, to your American correspondent. Few men knew more about Barry's career than the recently deceased Surgeon-General Sir T. Longmore, C.B., with whom I often corresponded on the subject, and who placed a copy of my novel in the Museum Library of the Victoria Hospital. But many other persons are, I believe, still to the fore who could furnish interesting reminiscences of this eccentric individual—notably, General Lowry, C.B., General W. Chamberlayne, General de Montmorenci, Colonel R. Wilson, and Surgeon-Major-Generals Tippetts and G. Langford Hine; all of them served from time to time with her at various foreign stations. I may add that she always seemed to have immense influence at headquarters and could almost choose her own station. Imperious in manner and officially dictatorial, in social circles she was admired and respected; she was, moreover, sympathetic and skilful in her profession—yet what a life of repressed emotions must hers have been?—a woman, too, who it was said gave birth to a child in her early days.

I am, Sirs, yours faithfully,

E. ROGERS, Lieutenant-Colonel,
(late Staff Officer of Pensioners and formerly Captain 3rd West India Regiment).

Netley, Oct. 15th, 1895.

To the Editors of THE LANCET.

SIRS,—At page 959 of THE LANCET you say: "Probably some of our readers can inform us and our correspondent with certainty about James Barry." I write to say that the medical officer so called travelled in a steamer of which I was the medical officer many years ago. In common with all on board, I was much struck with the peculiarities of that officer; and, I think, a notice of those has since appeared in one of the journals. The diet and the fondness for pets, the peculiar figure and appearance, all justified the ideas that were entertained about her at the time; and these ideas, it is said, were confirmed after her decease. It has been stated that this officer fought two duels; so it is evident that want of courage was not one of her weaknesses.

I am, Sirs, your obedient servant,

C. F. MOORE, M.D., F.R.C.S. Irel.

Upper Merrion-street, Dublin, Oct. 14th, 1895.

To the Editors of THE LANCET.

SIRS,—I see that you ask from your readers any particulars which may be known to them about Dr. James Barry. I heard of him (or her) from my old friend, Dr. Jobson, who, after spending many years as an army surgeon, finished his career as a physician in Kent. Dr. Jobson died about fifteen years ago, an old man aged about eighty-five years, so it must have been rather early in the century when he was at college in Edinburgh. One of his fellow students was remarkable by the persistency with which he avoided his fellow students, and was also laughed at because, in contradistinction to the shooting-coats which all the other students wore, he invariably appeared in a long surtout. However, although Barry kept the other students at a distance, he soon became friendly with Dr. Jobson and invited him to his lodgings, where he introduced him to his mother, with whom he lived. Both Dr. Jobson and Dr. Barry resolved to go into the army, and were together at a depôt where Dr. Jobson was astonished to find that Dr. Barry was afraid to go home by himself through a rather rough part of the town, but asked Dr. Jobson to go with him. Dr. Jobson, who, although a little man, was devoted to athletics, was much disappointed that he could not teach Dr. Barry to box. He never would strike out, but kept his arms over his chest to protect it from blows. Dr. Jobson and Dr. Barry were appointed to different regiments, and they never met again, although Dr. Jobson heard of him occasionally as performing all the duties of an army surgeon, and also of his performing serious operations in the hospital at Malta. When she died and it was discovered that she was a woman and had been a mother, Dr. Jobson was as much astonished as anybody; for, although he remembered the above-mentioned womanly traits, they had never caused him to have the slightest suspicion of her sex. What romance or tragedy led Dr. Barry to act as she did will not, I fancy, be ever known—at least, Dr. Jobson could never get any light upon it. As I myself am an old woman over sixty years of age I dare say there are not many people left who know anything about Dr. Barry, and I have thought these scanty particulars might interest your readers.

I am, Sirs, yours obediently,

India-street, Edinburgh, Oct. 14th, 1895. JANET CARPHIN.

To the Editors of THE LANCET.

SIRS,—There is no doubt of the existence of "James Barry," or of her sex. She lived some forty years ago in a street leading off Piccadilly—Down-street, I think. I lived in the same neighbourhood at that time, and knew her perfectly well by sight, and it was a matter of common repute that she belonged to a different sex than the one indicated by her clothes. Dr. Barry, as she was always called, was about 5 ft. 6 in. in height, slight in build, with a smooth, pale face. I saw her last in the year 1851 or 1852, and while in India later I remember reading of her death and of the discovery of the sex. She was a great friend of Lady Charles Somerset, who used to live near by in Piccadilly at that time. This information is not very definite, but it will help to assure Dr. Bright that "James Barry" is no figment, and that the story of her sex is undoubted. I am, Sirs, yours faithfully,

Oct. 16th, 1895. A.M.S.

To the Editors of THE LANCET.

SIRS,—Referring to Dr. Bright's queries under the above heading in THE LANCET of Oct. 12th, I beg to refer him to Dr. Meiring Beck of Rondebosch, Cape Town. Dr. Beck discovered reliable information concerning "Dr. James Barry," and read a most interesting paper on the subject to the Cape Town Branch of the British Medical Association, which was published in the *South African Medical Journal* about six months ago. It appears that "Dr. James Barry" served a useful career in the Army Medical Staff in Cape Colony, the West Indies, and, I think, also St. Helena. Her sex was not known until after death.

I am, Sirs, yours faithfully,

H. LAING GORDON, M.D. Edin.

Vincent-square, S.W., Oct. 14th, 1895.

Mr. J. C. Glenville.—We do not prescribe, and we do not recommend individual practitioners. We so far depart from our rule as to inform our correspondent that the method of treatment he desires is absolutely mythical, and we recommend him strongly to see a neighbouring surgeon.

Z.—We will inquire what M. Chauveau really said, and if we can learn definitely will communicate further through our columns. The newspaper cutting is, of course, absurd.

Kappa can only be advised to consult his medical attendant.

"THE PRESYSTOLIC APEX MURMUR WITHOUT MITRAL STENOSIS."

To the Editors of THE LANCET.

SIRS,—Dr. Arthur G. Phear's interesting article on the above subject, which appears in THE LANCET of Sept. 21st, makes me think it worth while to record the following case, which seems to indicate that a mere variation in the cardiac rhythm may give rise to a diastolic apex murmur.

A woman aged seventy years had constipation, nausea, and vomiting, with acute pain in the region of the vermiform appendix. The temperature was 99·5° F. and the pulse 100 per minute. The patient had previously had an attack of appendicitis. The bowels were opened with an enema. The vomiting ceased and the temperature became subnormal. There was a low-pitched, long, harsh diastolic apex murmur. There were no signs of cardiac hypertrophy and no other murmur. With ten-minim doses of tincture of digitalis every six hours the murmur completely disappeared in four days, and the pulse-rate was reduced to 83. The explanation offered is as follows. Normally the size of the ventricular cavity increases slowly during diastole and is kept quietly filled with blood. No diastolic murmur is then audible. But when the diastole is quickened the ventricular cavity increases too rapidly to be kept quietly filled. The flaps of the valve and the ventricular walls are deprived of their blood support, and the auriculo-ventricular stream is hastened by increased ventricular aspiration. Rapid diastole produces a hastened blood stream, flowing from one to another cavity upon unsupported muscular and tendinous structures that can be readily thrown into vibration. A diastolic murmur then becomes audible. It seems to me that in this case it was by slowing diastole that digitalis, combined, it may be, with the cessation of abdominal pain, caused the murmur to disappear. I am, Sirs, very truly yours,

Faseley, Tamworth, Oct. 14th, 1895. WILLIAM CATTO.

BOVRIL

BEEF  JELLY.

THE new package, adopted for this preparation, enables the beauty of the Jelly to be seen before opening. It is hermetically sealed, yet easier opened than any other package. Simply puncture the top; the vacuum is thus broken and the lid released. The Jelly will be found quite pure and free from all injurious contact with metal.

When this package once secures the attention of the Medical Profession no other will be used, as there is an increasing anxiety in the public mind about the action of tin and solder upon articles of food. **BEEF JELLY** is made from selected prime Ox Beef. It does not contain, as Bovril does, a high percentage of the albuminous or nitrogenous properties of meat; none of these jellies do, in spite of the veneration our parents had for calf's foot and other meat jellies.

This Essence of Beef can, however, be safely relied upon as an admirable stimulant and restorative in cases of nervous exhaustion, loss of blood, sudden shock, or in severe illness where no other food can be tolerated by the patient.

BOVRIL, LTD., FOOD SPECIALISTS, LONDON.

IDRIS

Telegrams: "IDRIS, CAMDEN TOWN." *Telephone No. 7522.*

Members of the Medical Profession are specially invited to pay a visit to IDRIS & Co.'s factory, which will be found to be one of the most complete and best equipped in the world.

ROYAL TABLE WATERS.

Many Physicians find that Aerated or Carbonated Waters are very pleasant and desirable vehicles for the administration of Alkaline Hypophosphites, Iodides, Bromides and Salicylates, Antipyrin, &c., &c. Medical Practitioners wishing to try any combination of medicines in aerated waters are requested to signify their wishes to any Chemist, with instructions to apply to IDRIS & Co.

Samples Free to Members of the Medical Profession.

IDRIS & CO., LTD., PRATT ST., CAMDEN TOWN, N.W.;
And at COLEMAN STREET, SOUTHAMPTON.

NESTLÉ'S CONDENSED SWISS MILK

THE RICHEST IN CREAM.

PERCENTAGE OF BUTTER FAT.

Six Samples of NESTLÉ'S MILK bought at random at six different Shops, and analyzed by Mr. OTTO HEHNER, late President of the Society of Public Analysts, contained AN AVERAGE OF

13·13 PER CENT. OF BUTTER FAT.

Sample Tin sent free to the Medical Profession on application to HENRI NESTLÉ, 48, Cannon Street, London, E.C.

The Latest Therapy of some Synthetic Remedies.

ANTIPYRIN.

The report of the British Medical Association Therapeutic Committee unmistakably proved that Antipyrin is more largely prescribed than any other antipyretic, and further established the superiority of this valuable therapeutic agent as an analgesic over both phenacetin and antifebrin. Since this highly satisfactory report was issued physicians have been constantly discovering new fields of usefulness for Antipyrin, and a short summary of these new developments may prove of interest.

Some new developments.

Many references will be found in the medical journals to the relief of typhoid, pneumonia, and chorea by its internal administration. As an anodyne in rheumatism and sciatica it is now extensively prescribed. In painful dysmenorrhœa it is recommended that the drug be administered as soon as there is any indication of the approach of the menses, and that it be continued for six doses. In several cases of urticaria with gastric symptoms the intense itching was relieved, and the rash disappeared on the exhibition of Antipyrin. It relieves the pains of locomotor ataxy and, in combination with morphine, that of incurable cancer also.

Favourable results are reported in a case of epilepsy in a boy of nine. A cure followed the administration of a dose of five (slowly increased to twenty-five) grains three times a day. It has proved of great value when administered hypodermically in cases of angina pectoris and of biliary and renal colic. In doses of five to ten grains it relieves facial neuralgia and sea-sickness. As a local anæsthetic, solutions of 35 to 50 per cent. are used in painful affections of the larynx. The effect is not so great as when cocaine is used, but is more prolonged. A 3 to 5 per cent. solution may also be used in the form of a spray in laryngo-tracheitis. The analgesic effect of this agent when thus applied to the mucous surfaces will last for some hours. This is the explanation possibly of its power as an antispasmodic, diminishing, as it does, reflex cough and asthma of nasal affections, and gagging and retching in pharyngitis, in which affections it generally answers well when other remedies have failed.

In epilepsy and sea-sickness.

In whooping-cough it may be claimed that Antipyrin has had considerable success. Attacks are said to be greatly diminished in intensity and to be of less frequency, particularly at night. Again, in the treatment of epistaxis, Antipyrin has been used with signal success, and in this connexion, as a hæmostatic, may be used in solution (from 5 to 10 per cent.) after intra-nasal operations, such as removal of spurs, polypi, &c. Even in ophthalmic practice (according to a continental report) this drug may be applied with advantage. For simple, acute, and chronic conjunctivitis a 3 to 5 per cent. solution is instilled twice or thrice daily, which solution may be used to diminish the pain in scleritis and episcleritis.

In whooping-cough and epistaxis.

"Tabloids" of Antipyrin may be had in two strengths—5 grains and 2½ grains—and these are highly convenient for the dispensing of this valuable drug. Bottles containing 100 sugar-coated 2½ gr. "Tabloids" are supplied to the Medical Profession at 2/1 each, or similar bottles of 5 gr. "Tabloids" at 3/11.

Convenient administration.

DERMATOL.

This new and effective substitute for Iodoform is similar in appearance to that drug, but is ***entirely without odour.*** Dermatol is not hygroscopic and does not clog together. It is non-toxic, and, besides being powerfully antiseptic, exerts also a mildly astringent, drying action. Dr. Bluhm has tested its bactericidal power upon twelve different kinds of bacteria, comparing results with those obtainable with Iodoform, and finds the polyseptic action of Dermatol far superior to that of its repugnant predecessor.

An odourless substitute for Iodoform.

Dermatol has been used with excellent results in otitis media suppurativa, otitis externa, and in a large number of cases of chronic middle ear suppuration. The secretion was quickly reduced in quantity, and "most of the cases ceased suppuration after a few insufflations."

In many diseases of the ear and nasopharynx it may be applied with excellent effect; it has been used with very good results in treating venereal ulcers; and, suspended in diluted lanoline (lanoline one part, paroleine nine), has been recommended as highly serviceable in acute urethritis. Professor Colasanti and Dr. Dutto of Rome have administered it with the greatest success in various diarrhœic conditions. In 100 cases of the colliquative diarrhœa of consumptives improvement under administration of doses of seven grains Dermatol given four times a day was observable within twenty-four hours. The same treatment also answered all expectations in numerous cases of typhoid and malarial diarrhœa, enterocolitis, and in convalescence from acute febrile diseases, where the diarrhœa had resisted all other forms of treatment.

In aural practice.

Dermatol rapidly absorbs wound secretions, and forms a very hard, dense, and closely adherent crust, hence it proves exceedingly useful in all cases where astringent and drying effects are desirable. It is adapted for use in crushed or lacerated non-septic wounds, burns and scalds, moist eczema and intertrigo, also in large crural ulcers. Numerous cases are reported of the value of Dermatol in chronic skin diseases of a suppurative nature. Dermatol undoubtedly deserves the attention of gynæcologists in view of the experience related at the Bonn Gynæcological Congress. Remarkably satisfactory results were obtained by its use in the treatment of laparotomy wounds, prevalent carcinomata, myomata, deep-seated tuberculous peritoneal abscess, infectious catarrhs of vagina, cervix, or endometrium. He finds it far superior to Iodoform and concludes: "Dermatol is absolutely unirritating, powerfully antiseptic, astringent, odourless, stable, and non-hydroscopic."

In gynæcological practice.

For the internal administration of Dermatol, "Tabloids" may be had containing 4 grains.

Dusted upon a freshly cauterised surface it kills the pain at once.

The astringent, drying, and soothing properties of Dermatol peculiarly adapt it for toilet purposes, and we accordingly prepare it in the form of a Dusting Powder. This is a perfectly neutral, non-irritating Toilet and Nursery Powder. It allays irritation. It may be substituted with advantage for Violet Powder and Fuller's Earth for the nursery and toilet, as it possesses more pronounced healing and soothing properties. Supplied in suitable boxes for dusting, with the powder, 1½ oz. each.

Dermatol Dusting Powder.

Maltine

THE preference of the Medical Profession for this valuable Food-Digestant is abundantly justified by the results of an every-day clinical experience that has now extended over many years. It is, after all, the practice that tells, and had not results corresponded with expectations, "Maltine" would not have retained its high place among dietetic auxiliaries The valuable characteristics of "Maltine" are due to:—

A. THE MATERIALS EMPLOYED. The choicest grain only is used, that which lengthy observation has shown to be the best adapted for malting, giving the highest percentage of soluble nutritive material with the greatest diastasic potency.

B. THE PROCESS. This has as much to do with the quality of a malt extract as any other factors. From beginning to end, the manufacture of the extract involves chemical problems, the successful solution of which can only be obtained by the closest attention of the experienced chemist. To extract the maximum of the proximate principles from the grain—phosphates, albuminoids, maltose, dextrins; to obtain the utmost quantity possible of the delicate hydrolytic ferment, diastase, so liable to impairment, and to secure that the finished product shall have a pleasant flavour and an agreeable consistence, are achievements only to be realized by means of elaborate appliances, a carefully devised process, and the best technical supervision.

The favourable opinion of the Medical Profession regarding "Maltine" is the best evidence of its successful manufacture. Its pronounced effect on nutrition in cases of mal-assimilation and the rapid gain in weight that generally ensues from its use, show that it stimulates the digestive functions and furnishes the appropriate nutriment for such conditions. These general inferences are substantiated by scientific critics.

THE LANCET states: "'Maltine' exhibits in an eminent degree the starch dissolving power of diastase; in fact, a teaspoonful is capable of converting instantaneously a surprising amount of stiff starch paste into a thin limpid liquid."

The BRITISH MEDICAL JOURNAL concludes: "The greater nutritive value of this combination ('Maltine') is apparent. Clinical experience enables us to recommend it in virtue of its albuminoid contents and its richness in phosphates and diastase."

Dr. STUTZER affirms: "The nitrogenous substances which it contains are considerably richer than in any extract of malt known in the market. Phosphoric acid and potash are also present in 'Maltine' in a larger quantity than in any preparation of malt I have yet examined. As to diastase-converting power, 'Maltine' is far superior to the best extracts of malt I have ever seen."

Professor ATTFIELD found that "'Maltine' contains from three to five times as much diastase as any other extract of malt in the market." "Its flavour and odour," he declares, "are those of a delicate sweetmeat."

COD LIVER OIL.—As a food containing a large quantity of fat-making and heat-giving properties, "Maltine" is frequently prescribed for patients intolerant of cod liver oil. When, however, the ingestion of fat is deemed essential,

Maltine WITH COD LIVER OIL

furnishes this valuable oil in a form which cannot possibly disagree. By careful incorporation with the "Maltine," the oil is so perfectly broken up that it is administered in a condition ready for immediate assimilation. As regards concealment of fishy taste and odour, "Maltine" with Cod Liver Oil has reached a perfection never before attained in the preparation of palatable forms of cod liver oil.

The BRITISH MEDICAL JOURNAL says of "Maltine" with Cod Liver Oil: "Patients unable to tolerate the purest and most carefully prepared Cod Liver Oil can readily digest and assimilate it when combined with 'Maltine.'"

WE SHALL BE PLEASED TO SEND SAMPLES FREE OF CHARGE & CARRIAGE PAID TO MEDICAL MEN.

In prescribing, please specify "MALTINE CO."

The Harveian Oration
ON
HARVEY AND THE RISE OF PHYSIOLOGY IN ENGLAND.

Delivered before the Royal College of Physicians of London on Oct. 18th, 1895,

BY W. S. CHURCH, M.D.OXON., F.R.C.P.LOND.,
SENIOR PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

MR. PRESIDENT,—In obeying your request that I should undertake the delivery of the Harveian Oration I am painfully sensible of the gravity of the task you have imposed on me. For 239 years, with but few intermissions, the College has, in obedience to Harvey's own wishes, assembled to commemorate its benefactors, and if we can no longer precisely follow Harvey's directions and "commemorate all the benefactors of the said College by name, and what in particular they have done for the benefit of the College," the remainder of his words are still applicable, for part of the Harveian orator's duty is "to exhort others to imitate those benefactors, and to contribute their endeavours for the advancement of the society according to the example of those benefactors." This annual office has been filled during the years that have elapsed since Harvey's institution of it by some of the most illustrious Fellows on our roll—by Garth (1697), Arbuthnot (1727), and Akenside (1759); by Mead (1723), Heberden (1750), and Warren (1768), not to mention others of more recent date, men whose names will ever remain fresh in the history of the literature and medicine of our country. I have no claim to be associated with these great names, nor with the many learned and eloquent men who have addressed you in recent years, and I should have shrunk from attempting the task your favour has imposed on me had I not felt that in asking me to undertake it you were mindful of the position which it is my lot to hold in connexion with the great hospital to which the immortal Harvey was thirty-four years physician, in which he exercised an influence over its governing body that remains to this day, and where his memory is yet held in reverential remembrance. I wish it were possible for me to bring forward from the records of St. Bartholomew's Hospital any new facts illustrating either Harvey's life or works; but many years ago Sir James Paget, in his "Records of Harvey," exhausted all that is known of him from the journals of our hospital. In the fragmentary notices of him which we there meet with he is seen as the trusted adviser to the governing body and as the maintainer of the dignity of his order rather than as the physician. In his "Prælectiones Anatomicæ Universalis" we obtain glimpses of his work in the wards of the hospital, and had his "Medical Observations" come down to us there can be little doubt that in them much would have been found which emanated from the wards of the hospital and the dissections of patients who died whilst under treatment there.

Foremost among the benefactors to our College present to the mind of Harvey when he established this annual Oration must have been Dr. Richard Caldwell and Lord Lumley, who together founded and endowed in 1581 the Surgery Lecture which, under the name of the Lumleian Lecture, Harvey held from 1615 until 1656, and in the course of which he demonstrated to the College his immortal discovery. I have failed to find out the nature of the connexion, if any, between Caldwell and Lord Lumley. The latter succeeded his father, Lord Arundel, as High Steward of the University of Oxford in the year 1558, the year before Caldwell appears to have completely severed his connexion with the University. Of Lord Lumley, Camden says "that he was a person of entire virtue, integrity, and innocence, and in his old age a complete pattern of true nobility." By the kindness of our registrar my attention has been drawn to the very interesting notice of Caldwell in Hollinshed's "Chronicles," where an account is given of the first lecture delivered under the terms of this bequest by Dr. Richard Forster, "which was celebrated by a goodlie assemblie of Doctors, Collegiate and Licentiate, as also some Masters of Surgerie, with other students, some whereof had been Academical. Dr. Caldwell, his white head adding double reverence to his person, notwithstanding his age and impotencie, made an Oration in Latin to the auditorie, the same by occasion of his manifest debilities unfinished at the direction speciallie of the President: who after a few words shortlie and sweetlie utered, gave occasion and opportunity to Dr. Forster, then and yet the appointed Lecturer, to deliver his matter." It is impossible for me to mention the long list of those who, by their munificence or by the honour which their lives and labours have bestowed on the College, have to be commemorated as benefactors since the days of Harvey. Within the present year we have had a notable example, not only of the generosity, but what is still more to be desired, of the brotherly feeling which Harvey desired should exist among us. No one among our Fellows has during the last fifty years been a brighter ornament to this College or a greater benefactor to his country or the world at large than Edmund Alexander Parkes. It must be a source of gratification to us all that Dr. Hermann Weber, when generously endowing the College with the magnificent sum of £3000 for the furtherance of original research on the "Prevention and Cure of Tuberculosis," should have associated Dr. Parkes's honoured name with his own. The triennial prize, which the College has decided to found with this bequest, will tend, let us hope, not only to keep fresh in the memories of many generations of Fellows the genial and liberal donor and his valued friend, but may accomplish the object of the giver and lead to future discoveries by which the ravages of tuberculous disease may be controlled and abated, if not altogether prevented.

It may interest the College to know that the subject selected for the first competition is "The Means, Prophylactic or Curative, deemed by the Author to have Value in the Control of Tuberculosis, especial Regard being had to their Application to Human Tuberculosis." I should like to pause here to set before you at somewhat greater length the useful, pure, and unselfish life of Dr. Parkes and to recall to your memory the excellence of his scientific work in connexion with the ingestion and elimination of nitrogen in the system, as well as to draw your attention to the benefits which our naval and military services and the general public have received from his labours in the field of hygiene; but I must pass on now and content myself with thus briefly alluding to the munificent gift of Dr. Hermann Weber and the memory of Edmund Alexander Parkes.[1]

Harvey's fame is immortal, and he is to be placed in the same category with Hippocrates, Aristotle, Archimedes, and Newton, who by their genius may be looked upon as not so much the exponents as the founders of their respective branches of knowledge. Aristotle was the first, and in a sense the greatest, of biologists. Harvey was the founder of physiology. Harvey himself was an Aristotelian, educated in all the learning of the schoolmen; and in attempting to estimate his genius and originality it is almost impossible for us in these days of independent thought to realise the crushing influence which authority then exercised on the minds of men; in the words of Dryden, they

> "betrayed
> Their freeborn reason to the Stagyrite
> And made his torch their universal light."[2]

As in medicine, although there must have been practitioners before the days of Hippocrates, he is to be taken as the starting point, so in biology, notwithstanding the labours of Parmenides, Empedocles, and others of still earlier date whose writings are known to us but by fragments, Aristotle stands alone as the originator of biological science. He, together with his immediate successors, took, as has been observed by Professor Huxley,[3] "the broadest view of the subject, and man assumed his place as neither more nor less scientifically interesting than his fellows." Harvey's admiration of Aristotle is profound; he calls him the supreme dictator in philosophy, and in the introduction to the "De Generatione Animalium" says: "Foremost among the ancients I follow Aristotle; he is my leader." Dr. W. Ogle, in the preface to his excellent translation of Aristotle's work "On the Parts of Animals," says most justly: "The biological treatises of Aristotle are more often quoted than read, and, it may be added, much more often misquoted than correctly quoted." The prominent feature of Aristotle's biological

writings, as, indeed, of his philosophy generally, is classification, in which respect his writings contrast strongly with the poetical and imaginative treatises of his forerunner Plato. From the time of Aristotle to that of Harvey no advance was made in physiological knowledge; in truth it had receded, overwhelmed by the glosses and erroneous interpretations so often put on Aristotle's writings.

In attempting to estimate Harvey's merits as a discoverer it is necessary for us as far as possible to realise the state of knowledge at the commencement of the seventeenth century, and the nature of his surroundings. Subsequently to the time of Aristotle, who was very imperfectly acquainted, as he himself admits, with human anatomy, the Alexandrian school, where the two rivals, Erasistratus and Hierophilus, practised human dissection, had considerably advanced human anatomy; their observations and discoveries were made use of by Galen, who added to anatomical knowledge by his accurate dissections of the lower animals, including apes. The anatomical facts thus observed were of comparatively little use through their being treated as disjointed observations; thus there can be no doubt that Erasistratus observed the lacteals in the mesentery of sucking kids hundreds of years before Aselli rediscovered them in dogs; and Aselli's observations would have proved as barren as Erasistratus's had Pecquet not traced the lacteals to the receptaculum chyli and thoracic duct, which vessel had many years before been noticed by Eustachius in the thorax of a horse, and described by him as the vena alba thoracis. With the revival of learning human anatomy began to be studied on account of its obvious bearing on medicine and surgery, and by Harvey's time, owing to the labours of Mundinus, Sylvius, Eustachius, Vesalius, Fallopius, and others, the details of the bodily structure of man observable by the unassisted eye were for the most part discovered. In physiology, on the other hand, there had been no advance whatever, unless the very imperfect knowledge of the lesser circulation be considered as having a claim to be so regarded. It in no way detracts from Harvey's merit or originality that Servetus, Columbus, and Cesalpinus all had an idea of the lesser circulation, without, however, comprehending it or seeing to what it led, or that Fabricius had demonstrated beyond doubt the existence of the valves in the veins. Dugald Stewart has remarked: "In the sciences the observations and conjectures of obscure individuals on the subjects which are level to their capacities, and which fall under their own immediate notice, accumulate for a course of years, till at last some philosopher arises who combines these scattered materials, and exhibits in his system, not merely the force of a single man, but the intellectual power of the age in which he lives."[4] Regard must also be paid to the spirit of the times, and the remarkable uprising of independent thought and inquiry which characterises the century immediately preceding Harvey's birth.

Bacon is frequently spoken of as the founder of inductive philosophy and the destroyer of the syllogistic reasoning which had been all-powerful before his day. This may be true when applied to moral philosophy, but is certainly not so when we consider physical or natural philosophy. In his biological writings Aristotle makes constant use of the inductive process, and he points out that it is absurd to suppose that syllogistic reasoning could lead to the discovery of any new principles;[5] and again he says, still more definitely, "that reasoning is naturally prior and more known that proceeds by syllogism, yet is that more perspicuous to us which is based on induction."[6] Aristotle's inveterate custom of specifying a final cause for every structure and organ which he came across in the animal body not only led him into many absurdly erroneous conclusions, but—joined with the oft-quoted maxim of Bacon, "Causarum finalium inquisitio sterilis est, et tanquam virgo, Deo consecrata, nihil parit"—has led to the wonderful work he did in biology being less thoroughly appreciated by us than it deserves. Bacon's objection to the consideration of final causes in physics was owing to his belief that it "banished the study of physical causes; the fancy amusing itself with illusory explanations derived from the former." That Bacon was wrong in this view is proved by Harvey himself, for we have it in his own words, as reported by Boyle,[7] that it was from studying the valves of the veins, and believing "that so provident a cause as nature had not placed so many valves without design," that he was first induced to think of a circulation of the blood. Equally false is the belief very generally held that Bacon was the first to revolt from the tyranny of the Aristotelian school. The alliance which had taken place between the Papal Church and the Aristotelians caused those who at the Reformation refused to recognise the infallibility of the Church of Rome also to throw off their allegiance to the tenets of the schools. Luther and Calvin, not to mention lesser men, declared that no man could be an Aristotelian and a Christian; and St. Paul's warning, "Beware lest any man spoil you through philosophy and vain deceit after the tradition of men."[8] was a favourite text for the ministers of the Reformation to expound. The same spirit of inquiry which broke down the tyranny of the Church also freed men's minds from the trammels of the dogmas of the current philosophy. The physicists, by questioning the accepted doctrines of the nature of the universe, were the first to commence this healthy movement, and the widespread popularity of Ramus's teaching very greatly expedited the change which occurred. Ramus, from the commencement of his career, disputed the authority of Aristotle, and may be said to have spent his whole life in opposing the orthodox philosophy of the times, and perished a martyr to his opinions and the rancour of his opponents in the massacre of St. Bartholomew's Day (1572). Harvey, when at Padua, must have been in the midst of the conflicting theories and bitter controversies of the Aristotelians and their opponents. His even and well-balanced mind prevented his joining either party. Throughout all his writings he pays the greatest respect to Aristotle, and takes him as his main guide in his work, "De Generatione Animalium." He makes also constant references to him in his "Prælectiones Anatomicæ Universalis"; and when Aubrey asked him what he should read bid him go to the fountain head and read Aristotle, Cicero, and Avicenna. The same authority tells us that Harvey, whilst esteeming Bacon much for his wit and style, was not enamoured of his philosophy. It would be interesting to know how intimate Harvey was with the Lord Chancellor, and whether their communications merely partook of the character of physician and patient, or whether Harvey discussed philosophical questions with the older man.

My predecessors in this office have so fully vindicated Harvey's claim to the discovery of the circulation against the attempts which have been made within recent years to deprive our countrymen of this honour that I will pass on, merely thanking Sir Edward Sieveking and Sir George Johnson for the able and triumphant manner in which they have refuted the statements put forward in favour of Cesalpinus as the true discoverer of the circulation of the blood. Neither Servetus, Columbus, nor Cesalpinus in any way anticipated Harvey, who not only discovered the greater circulation, but demonstrated it and explained the true motion of the heart. He, and he alone, recognised the muscularity of the heart's wall, and perceived and demonstrated that it was the contractile power of the heart which was the primary cause of the pulse and of the circulation of the blood through both systemic and pulmonary vessels. Harvey, by a chain of close and acute reasoning drawn from direct experiments and from observations on the pulsation in aneurysms and in vessels distal to aneurysmal dilatations and to portions of rigid and calcified arteries, demonstrated once for all that the motion and contraction of the heart was the main, though not the only, cause of the pulse. Leaving thus the "Excitatio Anatomica de Motû Cordis et Sanguinis," I wish to consider that which Harvey's discovery rendered possible—the rise of physiology—more especially in England, and the part which Harvey himself took in founding it.

It must be always borne in mind that but a portion of Harvey's work has come down to us. We gather from his extant writings that he had collected materials for, if not composed and completed, the following treatises: "Observationes de Usû Lienis," "Observationes de Motû Locali," and "Tractatum Physiologicum de Amore Libidine et Coitû Animalium." We do not know how far advanced his "Medical Observations," to which he makes frequent references; his disquisitions on the "Cause, Uses, and Organs of Respiration"; his "Medical Anatomy," or "Anatomy in its Application to Medicine," may have been. Harvey announces, in his first disquisition to Riolanus, his "intention of putting to press this last work," and it must be regarded as an

irreparable loss that the world should have been deprived of the material he had collected, for one cannot doubt that his "Medical Anatomy" would have displayed the same master mind as is shown in his other works, and that morbid anatomy would have been advanced to the position it was placed in a hundred years later by Morgagni. As it is, we have to collect Harvey's general views of physiology from scattered passages in his works. Next to his "Exercitatio Anatomica de Motû Cordis et Sanguinis," his most important work is "De Generatione Animalium." This is an unfinished work. Harvey had probably intended to publish a larger and more complete treatise, but had failed to satisfy himself on the subject of generation, and what he was persuaded by Sir G. Ent to entrust to him for publication were but the exercises from which Harvey had intended to compile his work. Possibly the loss of his "Observations on the Generation of Insects" prevented his undertaking the larger work; but no one who reads the treatise will come to the opinion that Harvey was prepared to publish it in the shape in which we now have it. In the exercises we find much repetition both of words and ideas, much speculative matter on which he expresses no opinion. Not having satisfied himself as to the facts of generation he allows himself to be under the influence of the

"Master Sage of those who know"[9]—

and permits himself to wander off from observed facts into the shadowy but enticing realms of fancy and metaphysics. It is no detraction from Harvey's merit that he failed in understanding the nature of generation. The necessary means were not in existence; the simple magnifying glasses used for the inspection of the *punctum saliens* were unable to show him his error in supposing that the male element did not enter the uterus—a conclusion he came to after repeated inspections. Writing of the uterus of the doe after copulation he says: "I began to doubt, to ask myself whether the semen of the male could by any possibility make its way by attraction or injection to the seat of conception; and repeated examination led me to the conclusion that none of the semen reached this seat" (Exercise LXVII.); and in another place (Exercise L.) he asks "whether the conception of the uterus be of the same nature or not with the conceptions of the brain, and fecundity be acquired in the same way as knowledge—a conclusion in favour of which there is no lack of argument"; and in his essay on Conception he gives us what I imagine was his final conclusion: "The woman, after contact with the spermatic fluid *in coitû*, seems to receive an influence and become fecundated without the coöperation of any sensible corporeal agent, in the same way as iron touched by the magnet is endowed with its powers." The aphorism *Omne vivum ex ovo* is ascribed to Harvey, and often quoted as if he made use of the expression. It is true that at the end of his consideration of the development of the egg he concludes by quoting Aristotle with approval: "All living creatures, whether they swim, walk, or fly, and whether they come into the world in the form of an animal or of an egg, are engendered in the same manner." But it is quite evident from many passages in his treatise that Harvey did not unconditionally reject the doctrine of spontaneous generation. In Exercise LXIII., after stating "now we at the very outset of our observations asserted that all animals were in some sort produced from eggs," he goes on to explain his meaning more fully: "An egg is a conception exposed beyond the body of the parent whence the embryo is produced. Let us therefore say that that which is called *primordium* among things arising spontaneously, and seen among plants, is an egg among oviparous animals; the prime conception in viviparous animals is of the same precise nature"; and earlier in Exercise XLV., when discussing the difference between epigenesis and metamorphosis, he says: "Some animals are born of their own accord, concocted out of matter spontaneously." Harvey showed that the mode of development and growth was the same in the embryos of viviparous and oviparous animals, and maintained that in creatures said to arise spontaneously or to take their origin from putrefaction, filth, &c., the same developmental changes occurred; but nowhere expresses an opinion as to the origin of the ova themselves, although it is probable that he inclined to the belief that they were "propagated from elements and seeds so small as to be inconspicuous (like atoms flying in the air) scattered or dispersed here and there by the winds" (Exercise XLIII.). In the same way he expresses no opinion as to the origin of the animalcules generated in our bodies, and of the worms produced from plants and their fruit or from gall-nuts, the dog rose and various other galls, contenting himself with remarking that the living principle of the animals thus arising cannot have existed in the plants on whose juices they live (Exercise XXVII.).

Though misled from the want of proper means for observation in the fundamental facts of generation, there is much touching general physiology scattered through the treatise which is extremely interesting. Harvey remarks that he was the first to note that the bronchia or ends of the trachea in birds open into air sacs in the abdominal cavity (Exercise III.), an observation which, so far as I know, attracted no attention and did not receive confirmation until John Hunter demonstrated these air sacs afresh, and showed that the bronchia in birds were continuous also with the hollow spaces in their bones. In Exercise LVI. he has anticipated Darwin's explanation of sexual adornments, remarking: "Ornaments of all kinds, such as tufts, crests, combs, wattles, brilliant plumage, and the like, of which some vain creatures seem not a little proud, are most conspicuous in the male at that epoch when the females come into season, and whilst in the young they are still absent, in the aged they also fail as being no longer wanted." Hereditary likeness did not escape him, or that form which is spoken of as atavism, for he asks, "Why the offspring should at one time bear a stronger resemblance to the father, at another to the mother, and at a third to progenitors, both maternal and paternal, further removed" (Exercise LXII.). After the circulation of the blood and the mysteries of generation the subject which appears to have had most attraction for Harvey was that of "innate heat"—*calidum innatum*—the θέρμη ἐμφύτη of Aretæus, a term by which more was meant than the temperature, although that was the sensible evidence of it. Harvey distinguished the *anima*—soul or vital principle—from the innate heat. To the consideration of the latter he devotes Exercise LXXI., and treats at length of the former in Exercises XXVI. and XXVII. It would take me too long to attempt to give a sketch of his views of the *anima;* it is clear that he himself was dissatisfied with his own conception of the vital principle or *anima*, for he says in Exercise XXVIII., speaking of the way in which the egg is produced, "leaving points which are doubtful and disquisitions bearing upon the general question (that is, on the *anima*), we now approach more definite and obvious matters." Animal heat before the knowledge of the production of heat by chemical union was an inscrutable mystery which not even the genius of Harvey could penetrate. The maintenance of animal heat was supposed to be the gift of the heart to the blood; the belief that the heart was the source of heat was universally held by the ancients, Aristotle saying "that its wall is thick that it may serve to protect the source of heat."[10] This Aristotelian doctrine Harvey dissented from and destroyed by reasoning little less cogent than that by which he demonstrated the circulation, although he was unable to account for the presence of animal heat and imagined that it was inherent in the nature of blood and of divine origin. His words are so grand and poetic that I may be permitted to quote them at length: "I say that innate heat and the blood are not fire, neither do they derive their origin from fire. They rather share the nature of some other and that a more divine body and substance. They act by no faculty or property of the elements; but as there is something inherent in the semen which makes it prolific, and as in producing an animal it surpasses the powers of the elements—as it is a spirit, namely, and the inherent nature of that spirit corresponds to the essence of the stars—so there is a spirit of certain force inherent in the blood acting superiorly to the powers of the elements, very conspicuously displayed in the nutrition and preservation of the several parts of the animal body; and the nature, yea, the soul in the spirit and blood, is identical with the essence of the stars" (Exercise LXXI.). This outburst of Harvey is most striking, so unlike his usual manner, and one cannot but be astonished at his inconsistency, for it occurs in the same exercise as the following shrewd and calm remark: "We are too much in the habit, neglecting things, of worshipping names. The word blood, signifying a substance which we have before our eyes and can touch, has nothing of grandiloquence about it, but before such titles as spirit and *calidum innatum*, or innate heat, we stand agape," for assuredly the substitution of the phrase that the nature inherent in the blood was responsive to the essence of the

[9] Dante's "Inferno," Cant. iv., l. 131.

[10] De Part. Animalium, book iii., chap. 4.

Digitized by Google

stars is not less calculated to set us wondering than is the term "*calidum innatum*." Harvey, nevertheless, disproved for once and all the doctrine that the heart was the source of heat; he showed how animal heat was dependent on the due circulation of the blood and that the belief that the functions of the lungs were to cool the heated blood was absurd. He says: "The blood, instead of receiving, rather gives heat to the heart, as it does to all parts of the body; and it is on this account that the heart is furnished with coronary arteries and veins; it is for the same reason that other parts have vessels—namely, to secure the access of warmth for their due conservation and stimulation, so that the warmer any part is the greater its supply of blood, or otherwise—where the blood is in the largest quantity there also is the heat the highest." The "Prælectiones" are but notes to assist Harvey whilst lecturing, and it is therefore impossible to know what interpretation to place on them, but I think it highly probable that in the course of years Harvey, as his physiological knowledge increased, modified his views of the connexion between animal heat and the heart, for in the "Prælectiones" he speaks of the heart as the *fons totius caloris*, and calls it *arx et domicilium caloris* from which it appears that in 1616 he still held the Aristotelian opinion as to the heart as the source of heat. No portion of the "Prælectiones" show more strikingly the closeness of Harvey's observation, the amount of his knowledge, and the acumen of his reasoning than that relating to the exposition of the anatomy and the functions of the lungs. In his description of them and the pleuræ he makes constant references to their morbid anatomy and their embryonic condition. He is evidently in doubt whether the lungs expand and contract from their own movements or merely follow the movements of the thorax—a question which was afterwards fully investigated and explained by Mayow. The immediate followers of Harvey naturally turned their attention to the subjects on which he had thrown so much light—the circulation and respiration. Most notable among them were two distinguished Cornishmen, Richard Lower and John Mayow; the former is the best known from his experiments on the transfusion of blood, which attracted the attention of the general public, but those experiments are by no means the most important of his physiological researches; in addition to demonstrating in many ways that the red colour of arterial blood was due to the action of the air, he calculated the force of the heart and the quantity of the blood passing through it. He showed also by demonstrations on dogs that œdema of the parts distal to the heart followed ligature of the veins, and produced ascites by tying the vena cava in the thorax. Lower also was the first to show the dependence of the heart's action on nervous influence and to demonstrate the moderating effect of the pneumogastric nerve on the heart.

Mayow, though recognising that there was an interchange between the blood and air in the lungs, still thought that the source of vital heat was in the heart, "not that it contained a biolychnium (that is, a vital torch) flaring within it, but that from its perpetual motion for carrying on the circulation the nitro-aerial and sulphureous particles in it must be in a state of perpetual effervescence, and that necessarily remarkable heat must be excited."[11] Mayow thought that air was impregnated with a certain universal salt, which was of the nature of nitre, and with vital spirit, and with fire; notwithstanding this erroneous view of the nature of air, it is remarkable how closely his explanation of the action of this imaginary salt on the blood agrees with the actual action of oxygen, and he sums up his conclusions as to the uses of respiration as follows: "Life consists in the distribution of animal spirits which must be supplied for the pulsation of the heart. In very truth it is highly probable that the aerial salt is necessary for any muscular movement, so that without it no pulsation of the heart is possible."[12] In his essay "De Respiratione Fœtus in Utero et Ovo" he correctly infers that the blood of the fœtus obtained through the umbilical arteries not only nourishment, but also aerial salts which obviated the necessity of functional activity in the lungs during intra-uterine life, and states definitely that the placenta should not be regarded as an amplified liver, but as a uterine lung. It is not for his chemico-vital theories alone that Mayow deserves to be remembered; he first accurately described the action of the intercostal muscles and diaphragm, and showed that inflation of the lungs depended on atmospheric pressure. It was not until upwards of a hundred years later, when Black had shown the presence of carbonic acid in expired air and investigated the phenomena of latent and sensible heat, when Priestley had isolated oxygen, and Cavendish and Lavoisier had completed the analysis of atmospheric air, that any real progress could be made in the study of respiration and animal or vital heat. Even now we are by no means fully acquainted with this most complex and difficult subject. Your Croonian Lecturer pointed out a few months ago some of the many difficulties which still have to be surmounted before we can arrive at an adequate knowledge of how and where the interchange between the oxygen of the air and the tissues takes place, and how our systems accommodate themselves to the changes of pressure and temperature in the air, so as to maintain the animal heat at a uniform level.

[11] De Spiritibus Animalibus, chap. iv., p. 31.
[12] De Respiratione.

I have endeavoured, very imperfectly I fear, to set before you the rise of physiology in England. Before the discovery of the circulation of the blood a right understanding of the means by which life is carried on was impossible, and Harvey's discovery should rank on the same level as Newton's discovery of gravitation. In both cases others had to a certain extent prepared the way and may have had glimpses of the truth, but to them the truth was revealed, and they might say with Tennyson's Holy Sage,

> "Idle gleams to thee are light to me,"

and the light which their genius led them to perceive enabled their successors to reveal what we now know of the mysteries of animate and inanimate nature. We know very little of Harvey's practice as a physician; what little we can gather from his writings show him to have been fertile in resource and skilful in the management of gynæcological cases. We cannot doubt that one who showed such acumen in deciphering the problems of life, and who speaks so wisely of the necessity for the study of morbid anatomy, must have been far ahead of the rest of his contemporaries in the application of his knowledge to clinical work; and the disparaging gossip of Aubrey merely reflects the opinions of those too ignorant and too bigoted to appreciate him.

I have already spoken of the overpowering authority of Aristotle over the minds of the students of nature, but the completeness of his dominion was not to be compared to the overwhelming influence of Galen in the medical world during the sixteenth and early part of the seventeenth centuries, and it needed yet another than Harvey to enable men to throw off the benumbing mantle of Galen. Our College annals recount, as pointed out by our learned librarian in his Roll of the College, that in the year 1559 Dr. Geynes was refused the Fellowship because he had ventured to doubt the infallibility of Galen; and in our annals it is stated that Dr. Hook was not granted admittance to the examination for the licence because he had the honesty to say that he had not read Galen. The revival of anatomy had by Harvey's time somewhat undermined the authority of Galen, which was still further impaired by Harvey's own discoveries. Nine years after Harvey's death appeared Sydenham's "Methodus Curandi Febris, Propriis Observationibus Superstructa," &c., and the world became aware that one had arisen who brought independent thought, unbiased by the traditions and views of the various schools of medicine, to bear on the study of disease. Our ignorance of the details of Sydenham's life renders it difficult to express an opinion as to the position he occupied in society or among his professional brethren in the year 1666, when the "Methodus" first appeared. He had then been settled in Westminster for ten years, and his intimacy during his Oxford life with Locke and Boyle, to whom he dedicates the work, makes it probable that from his first arrival in town he must have mixed with those bright and inquiring minds who instituted the Royal Society; be that as it may, his treatise at once attracted their attention, and in the same year in which it was published we find it reviewed in the "Philosophical Transactions of the Royal Society," then in the second year of its existence. I will not stay to consider how great or how small were Sydenham's literary acquirements, or whether he wrote his works in Latin or whether they were translated from the vernacular by Dr. Mapletoft and Mr. Havers; the subject is fully treated of by Dr. Latham in his "Life of Sydenham," and I know of no fresh evidence that has been obtained. Whatever may have been the amount of Sydenham's scholarship, no one who reads his works can fail to see from his

Digitized by Google

frequent allusions to Horace, Lucretius, Seneca, and others. that he was intimately acquainted with the Latin classics, and, like Dr. Latham, I should be sorry to consider that his admiration for Hippocrates—the divine old man—was taken at second hand. As to the other disputed point, whether Sydenham served as an officer in the Parliamentary army, the question has been set at rest by the discovery in the Record Office of a petition to the Lord Protector signed by Thomas Sydenham and endorsed "Captain Sydenham's Petition."[13]

Nurtured during the Civil War, the rough and turbulent early life of Sydenham left, perhaps, its stamp upon his character—a thoroughly upright, honest, God-fearing man, but somewhat intolerant of opposition, and of singular independence of mind. He had not the sweet nature of Harvey, which appears to have enabled that gifted man to have lived in peace with all men; but we must, I think, receive with caution the few contemporary anecdotes which have come down to us concerning him. It is pretty certain that Sydenham thought Sir Richard Blackmore a pedant and prig—an opinion shared by many, for, besides Dryden's well-known castigation of Sir Richard Blackmore, we have the following description of him by a contemporary:—

> "By Nature formed, by want a pedant made,
> Blackmore at first set up the whipping trade;
> Next quack commenced, when fierce with pride he swore
> That toothache, gout, and corns should be no more.
> In vain his drugs as well as birch he plied,
> His boys grew blockheads and his patients died."
>
> Col. Coddrington.

The oft-quoted story of the advice Sydenham gave him to read "Don Quixote" was probably only passing on that which Locke had given Sydenham, for the former says: "Of all the books of fiction, I know none that equals Cervantes's 'History of Don Quixote' in usefulness, pleasantness, and constant decorum."[14] And it may also have contained a covert allusion to the fictitious character of most medical writings. Sydenham's independence of mind is the key to his position in medicine. The opening paragraph in the preface to the first edition of the "Methodus Medendi" exhibits to us the serious and lofty view that Sydenham took of the physician's duty, whilst in the greatly expanded preface to the third edition he instructs us as to the means by which the science of medicine was to be advanced. It was his determination to study diseases as they presented themselves to him, keeping the peculiar and constant phenomena apart from the accidental and adventitious, and laying aside all hypotheses as to their nature, which enabled Sydenham to draw up those pictures of gout, dropsy, and fever which will remain classical for all time and justly entitle him to be called the modern Hippocrates. From Harvey's physiological teaching, and from clinical observations carried on in the spirit of Sydenham, our present knowledge of disease became possible. Harvey's work and writings had no direct influence on Sydenham; the latter makes no reference anywhere to Harvey, nor does he seem, in his treatise on "Dropsy," written in 1683, to have seen the bearing which Lower's experiments, made fourteen years previously, of ligature of the veins had on dropsy. Sydenham considered "weakness of the blood" to be the sole cause of dropsy, and throughout his writings he nowhere alludes to the physiology of the tissues. He quotes Hippocrates with approval, as blaming those who in their exceeding curiosity and officiousness busied themselves in speculations on the human frame, and, whilst admitting that more than one valuable medicine had been obtained from the chemists, blames those who thought that medicine could be promoted by the new chemical inventions of his day;[15] and he further on says: "The whole philosophy of medicine consists in working out the histories of diseases and applying the remedies which may dispel them; and experience is the sole guide."[16] Yet Sydenham himself had his theories, and, viewed by the light of our present knowledge, very incorrect ones, which were not in advance of those of his predecessors. Without theory—or, in other words, general principles—experience is a blind and useless guide. Rational theories of disease and its treatment can only be founded on physiological knowledge, and until, comparatively speaking, a very few years ago the knowledge of physiology and the knowledge of medicine were inseparably connected, for, with very few exceptions, the former was cultivated by medical practitioners alone, and may, without disrespect, be said to have been parasitic on medicine.

This is no longer the case, for using the term in its widest sense, as embracing the study of life, whether under normal or abnormal conditions, it has become the largest division of the natural sciences, throwing out like a gigantic tree huge branches from its main trunk, which depend more or less for support on chemistry and physics, and embracing within its ample boughs a vast series of subjects with whose rapid growth it is beyond the powers of any man to keep abreast. What is to be the future relation of it to medicine, or, rather, I should say, of medicine to physiology? The old position is reversed, and medicine—that is, the study of the manifestations of disease, its origin, course, and the means of alleviating its effects or preventing its occurrence—may be regarded as a branch of physiology, and one not less scientific than the observation of physiological phenomena in the laboratory. The practitioner of medicine turns to the physiologist, the bacteriologist, the chemist, and the physicist for aid in unravelling and explaining the symptoms he observes and has to deal with, and so long as they work together in the spirit which influenced Harvey and Sydenham—the pursuit of truth—the world must be the gainer.

The very brilliancy of recent discoveries and the vast increase in our knowledge may for a time react prejudicially on the art of medicine. Are we not in danger of being carried away by our enthusiasm? And may we not fall into the predicament, described many years ago by Buckle, of our facts outrunning our knowledge and encumbering our march? More especially does this difficulty arise in the training of our students; so vast is the range of subjects bearing on medicine, and so important does each appear to those best acquainted with them, that there seems to me danger lest, in endeavouring to secure an acquaintance with them all, we may forget that the future life of the majority of those entering our profession is to be spent in ministering to the victims of accident or disease, and that for the due recognition and treatment of sickness and injury experienced and trained clinical observation is absolutely necessary; no amount of laboratory training will enable a man to recognise the nature and proper mode of reduction of a dislocation, or know scabies when he sees it, and the words of Sydenham to his dear friend Dr. Mapletoft, "The art of medicine can be properly learned only from experience and exercise," will always hold good. There is no need to urge on the Fellows of the College another of Harvey's directions to the Orator of the day "to search out the secrets of nature by way of experiment," for at no period during the existence of our College have they manifested greater activity in that direction than at the present.

The great scientist who has recently passed away in the fulness of years and fame has opened to us new and most fascinating fields for future research, pregnant, I believe, with an abundant harvest of which he himself was permitted to see the first fruits; working out with scientific patience and accuracy the clue afforded by Jenner's discovery of the efficacy of vaccination in small-pox, Pasteur not only threw light on the darkness which surrounded the communicability of specific diseases, but placed in our hands a means to fight them. Pasteur has gone to his rest surrounded with all the honours a grateful nation could pay to his memory, and I know not that I can bestow a higher tribute to his genius than by saying that he will worthily be placed in the Temple of Fame by the side of our Harvey, both men honoured alike for the blameless character of their lives and the brilliancy of their discoveries. If we, as a nation, have not been able, through the action of our Legislature, to bear our full share in the furtherance of Pasteur's discoveries, we have at least the satisfaction that Lister was the first to recognise their bearing on morbific processes and to introduce new principles into surgery, which have added a hundredfold to its powers. The later developments of Pasteur's discoveries in the hands of Koch, Behring, Roux, Klein, and a host of equally earnest inquirers, have had in medicine a correspondingly important and beneficial effect on our conceptions of disease and its treatment. Remarkable as has been the nineteenth century in the development of science and its application to the needs of mankind, in no direction has it been more remarkable than in the progress of medicine. The introduction of anæsthetics marks the middle of the century, and its close will in the future be ever memorable as the era in which we commenced to have a truer and fuller insight into the causation and nature of disease

[13] A copy of the petition, together with other remarks, was published by Dr. Gee in St. Bartholomew's Hospital Reports, vol. xix., p. 1.

than the world had yet seen. Let us all, then, strive to work after the examples of Sydenham and Harvey, in the confident hope that as our knowledge advances we shall obtain greater powers of control over disease in all its forms and become provided with new and more potent means for the mitigation of pain and suffering.

An Address

ON

SOME OF THE CHANGES IN THE SURGERY OF THE LAST SIXTY YEARS.

Delivered at Oxford before the Medical Society on Oct. 18th, 1895,

BY SIR GEORGE MURRAY HUMPHRY.
M.D. CANTAB., F.R.S., &c.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF CAMBRIDGE.

GENTLEMEN,—On this day, fifty-nine years ago, my professional career commenced with an apprenticeship at Norwich, where I was initiated into the varied and practically useful work of a surgery under the direction and training of the most energetic and incessantly working, and one of the most learned and able, surgeons I have ever known, who, in spite of the engagements incidental to a large general and consulting practice, used regularly to examine me and my fellow pupils in our studies and who, in addition, gave me an early interest in the work of a pathological museum which has lasted through my life. It was no small privilege to be thus placed and to be a dresser and a case-taker in that Norwich Hospital which has been the scene of the labours of so many eminent physicians and surgeons. It was a happy time; I soon came to love the place and my work and those with whom I was associated, and it was, as you may suppose, a source of melancholy to me the other day, when I was there, to find that, owing to recent alterations (improvements?) in the regulations for medical study, there was not a single student to take advantage of that fertile field of knowledge and to take part with and stimulate and cheer the medical officers in their work. The Norwich Hospital without a student and the London hospitals overcrowded with them. This ought not to be. It is a grievous waste of practical opportunity and a serious loss to our profession and to the public that it is so. Having been on hospital duty as dresser, clinical clerk, or surgeon almost unremittingly from that day to this, at Norwich, St. Bartholomew's, and Addenbrooke's Hospitals, an unusually long and much favoured career, I do not know that I can better employ the time at our disposal than by giving a brief sketch of the changes I have witnessed in that period—changes which, in the main, have centred themselves about anæsthetics and antiseptics, and which rival the extraordinary social changes which have resulted from steam and electricity. In the museum to which I have referred there was a large ovarian cyst extracted through an incision in the linea alba successfully by Mr. Jeffreson of Framlingham. This was the forerunner of the marvellous results—the most marvellous, I think, in the history of surgery—which have since been attained in that direction by modern improvements. I well remember the respect with which I looked at and thought of this specimen in the days when tapping afforded the relief, and that a temporary one, from that distressing and fatal malady. There was also a calculus weighing fifteen ounces successfully extracted by a Norfolk surgeon in the presence and with the aid of Gooch and represented in his work on Surgery, and which stands, I believe, as the greatest triumph ever accomplished by the lateral operation of lithotomy. Now that operation, which was the pride and glory of my early life, which I thought one of the best and most unexceptionable of operations, seems in the way of being supplanted by litholapaxy and the supra-pubic method.

Let me narrate two cases which are good illustrations of the contrast between the past and the present. On the evening of Oct. 11th, 1838, a man aged twenty-six years, while carrying a sack of potatoes, fell with the right lower limb doubled under him, dislocating his hip into or above the sciatic notch. Attempts at reduction were made next morning at the Norwich Hospital by varied methods of manipulation and extension by pulleys. These were continued for four hours, during which time sixteen ounces and then twenty ounces of blood were drawn from the arm, and tartar emetic to the amount of twelve grains was given. Finally the man was taken to bed with the dislocation unreduced. He became feverish and delirious, with inflammation of the veins of the arm and about the hip: large abscesses formed and were opened in the hip and thigh, and after a lingering illness death ensued. One can scarcely conceive the occurrence of so disastrous an affair at the present time. In another case of a similar dislocation in a man of the same age, treated the morning after the accident at the same hospital in April, 1837, the same methods were applied; thirty ounces of blood were drawn, six grains of tartar emetic were administered, and not till after two hours and a half was reduction effected. The man recovered with a useful limb. Now, it is not too much to say that at the present day, in all probability, by the aid of an anæsthetic and the modern method of manipulation based upon better knowledge of the lesions accompanying the accident, the same surgeons would have reduced each of these dislocations in a few minutes. I say the same surgeons, for they were men of ability, well practised in surgery and supplied with the best apparatus and assistance which a large hospital provided at that time. The fault was not in them, but they had not the means and the additional knowledge which we now possess. We are no better than they, but we are better equipped to meet these and other contingencies in practice, and our patients are proportionately better off.

We dressers used to folow the surgeons round the hospital, each carrying a board laden with unguents and plasters and lint and tow, and a variety of appliances which were freely used in the dressing and redressing of wounds—too freely, as I even then ventured to think. The example and morale of Kneller's sagacious "Sympathetic Cure" made an early impression on my mind, and the plastering, undoing, and replastering of stumps, with the pulling at the ligatures and other devices which I saw practised, were a source of much distress to me, so that when I came to have the direction of affairs, as surgeon to Addenbrooke's Hospital, I discontinued these applications altogether, leaving the wounds, especially those after operations, freely exposed to the air without covering of any kind, the edges of course being united by sutures. The plan answered well, the wounds healed better than under the dressing method, the relief to the patient by the lessening of surgical interference was great, any discharge that escaped was easily cleaned away, and I regretted that other surgeons showed reluctance to adopt this simple open-air treatment. Happily, however, this good thing soon had to give way to a better—to the antiseptic—method, based upon a knowledge of the deleterious influence of air-borne micro-organisms, the ready acceptance of which throughout the civilised world has done more to extend the range, and promote the success, of surgery than anything in the whole history of our art; and the treatment of wounds, which was in my early days, and still more before them, the opprobrium, is now the glory, of surgery. Who would have dared in my early time to make exploring excursions about the peritoneal cavity, to cut into or remove a kidney, to cut out gall-stones, to open up the brain, and perform a variety of other operations, some of which are now of everyday occurrence—namely, excisions of joints and arthrectomy, radical cure of hernia and varicocele, removal of the thyroid gland and of the testes for senile prostatic disease, of the appendix cæci, the pylorus, and other portions of the intestinal canal, and the closure of perforating ulcers of the stomach. One day in the week used to suffice for the operating day; now a portion, often a considerable portion, of each day is in some hospitals devoted to this work. How greatly has the animal absorbable antiseptic ligature contributed to good results. Secondary hæmorrhage after operations, one of the sore trials of my early life and one of the sources of grave disaster to our patients, now scarcely ever occurs. The tied vessel heals without suppuration or ulceration, and is sealed whether a clot forms in its interior or not. Setons, moxas, and issues, in which we had much faith—at any rate, which we employed much—are almost forgotten, having given way to massage, douching, and other milder methods. That horrible compound, the black draught, the then so largely accredited

Digitized by Google

panacea, is now rarely administered, while such a host of new and milder remedies have entered the field that one almost wonders how disease can hold its ground at all. Curious problems are presented by the processes—the combinations of accident, observation, and reason—by which these various remedies have come into use and acquired confidence. Much might be written on this.

Perhaps the most extraordinary change which has taken place is in the matter of blood-letting. Persons, generally about middle age, used to come to the surgery at spring and fall to be blooded, and I calmly would take away, at a shilling a head, *pleno rivo*, sixteen or twenty ounces, and the good people did not seem the worse for the loss, either in body or pocket. What the real effect was upon them it would be interesting to know, and it would be still more interesting to know what would be the effect if the same procedure were now adopted. In the hospital also the lancet was freely employed in the treatment of a variety of inflammatory and other affections, and, as I have narrated, in the reduction of dislocations. How many medical men who have been fifteen or twenty years in practice have never seen venesection and do not know how to perform it. It has gone, as it were, out of the memory; it went suddenly, and it now scarcely occurs to the practitioner as a means of treatment. If it did occur to him he would be afraid to have recourse to such a proceeding, partly because it is so unwonted, so unknown, and partly for want of knowledge how to do it—that at least is the case with many. It is scarcely credible that so great a change in the use of so potent a weapon can have taken place in so short a time. One cannot help asking if the change is quite creditable. Either the over-use in the past must have been wrong or the total disuse in the present must be so—probably both; for the human constitution cannot have so altered in that period as to justify the change. The pendulum of fashion, we must admit, is not without its swing—its potent, its too potent, swing—in medical ideas and medical practice as in other matters, and I cannot doubt that venesection affords an illustration of such an influence. Nor can I doubt that lives are now often lost and maladies prolonged for the want of judicious recourse to it. Some years ago I was called to a middle-aged man of average strength suffering from an attack of severe pain in the chest (pleuritic) with the usual accompanying symptoms. In accordance too much with routine I prescribed the applications and medicines then in vogue. In a few days he died. A year afterwards I was called to his brother, the counterpart of himself, lying on the same bed with the same malady and precisely similar symptoms. I bled him to twenty ounces and in a few days he was well, leaving in my mind the conviction that had the treatment in the first case been like that in the second the result would have been the same. A man past middle life was suffering under dyspnœa with some bronchitis, labouring and intermitting action of heart, and albuminuria. To my suggestion of the loss of a few ounces of blood the surgeon in attendance replied: "What! bleed a man with intermitting pulse and albuminuria? You must bear the responsibility and carry out your treatment." I did so, taking about sixteen ounces from the arm, which was well borne and gave relief. Some months afterwards the surgeon, meeting me, said: "You saved that man's life; the bleeding was the right thing." I am glad to notice that the tide of feeling is ebbing a little and the opinion gaining ground that in some cases venesection may be resorted to with advantage. It is remarkable how well loss of blood from wounds is commonly borne, how in urgent cases the blood-stream may be supplied by warm water with a little salt, and how soon persons recover from prolonged and copious drainage of blood caused by uterine or rectal maladies. These experiences, together with those of bygone days, may give some courage to those who feel that venesection still deserves a place among the recognised means of combating disease.

Vaccination has not only proved one of the greatest boons that ever accrued to mankind through our profession, it has also been a source of profound interest and speculation, to me at least, for many years in a physiological and pathological point of view. Did it stand alone? Were its results altogether exceptional? Was the immunity from a given disease (small-pox), engendered by the insertion into the system of a minute quantity of the poison of that disease modified by its passage through another animal, to remain the solitary example of that kind of phenomenon, or were we to look for other like examples and the unveiling of new and far-reaching principles through them? I often wondered that the advocates of the "similia similibus" doctrine, in their vain efforts to find some reasonable ground for their theory, did not alight upon, or make more of the practice and results of, vaccination coupled with those of inoculation. Here was to hand the unmistakable evidence of a disease being hindered or prevented or stopped by the modification by the like, that is to say, of that which caused it. By inoculation—the introduction, that is, direct of the poison of small-pox—the disease was produced; by vaccination—the introduction of the like of that poison—the disease was prevented. Prevention and cure are near allies; and was it not possible, indeed probable, that cure might be effected by means like those which staved off disease? These thoughts often occurred to me and doubtless to others. It is no small thing to have lived to see these ideas confirmed, to learn that immunity from other diseases besides small-pox is attainable by the introduction into the system of minute quantities of the modified essences of the diseases, and to dwell now in the midst of the lively discussions and observations which are going on respecting the influence of similar methods in the cure of diseases. Should our hopes in the direction indicated be realised, it is scarcely too much to say that the greatest discovery, the one most conducive to the welfare of mankind, in our generation will have been made—a discovery in therapeutics surpassing even those of anæsthesia and antiseptic methods in surgery. Vaccination, moreover, has proved an illustration of the great principle that good is rarely unattended with evil, and, further, of the fact that many fail to estimate rightly between the good and the evil. It would be difficult to point out an instance where the good really preponderates so much as in vaccination, yet the clamour against it has necessitated a Royal Commission, and that commission finds difficulty in issuing its report and making suitable recommendations.

Greater accuracy in the diagnosis, the noting, and the treatment of disease, leading almost to revolution in several branches of our profession, has been effected by the microscope, the stethoscope, the ophthalmoscope, the laryngoscope, and the cystoscope—by the clinical thermometer as well as by the introduction of new instruments of various kinds, tempting possibly somewhat too much to their use, in the invention of which the skill of the surgeon and that of the mechanician vie with one another. All these alterations, which are for the most part improvements, and more especially the greater attention to sanitary arrangements, have led to a decided prolongation of human life as well as to a diminution of suffering.

While thinking over these changes, and others which time fails me to mention, in the means and surroundings which the last half century has brought to the medical man, and over the wide possibilities for good attendant on them, one cannot help wondering a little upon the medical man himself. He has accommodated himself well to the shifting of things about him. He has become accustomed to, and is more receptive of, new ideas. The *rôle* that he plays in the service of his fellow men has enlarged. He sees more of the world and enjoys the culture resulting therefrom. The dog-cart and the brougham are largely substituted for the saddle, and his life is altogether easier and more comfortable than it was. But as to the man himself the problem is more difficult. Greater opportunities and powers do not necessarily make greater or better men. When I recall the men with whom I was associated in my early life I bring before me so many of high stamp, of honourable feeling and upright character, professionally and generally well informed, highly revered by myself and others, the real trusted friends and advisers of their patients, that one may search in vain to find their superiors in the present generation. The dispensing and charging for medicines, then so general, never appeared to me to lower them in the estimation of others. Character and knowledge, then as now, were the bases of respect. Time has altered the surroundings much, but the men have changed little, which accords with the teachings of history in our own profession and the human race generally. The men of old were, as far as we can judge, as great and as good as those of to-day; and whatever comparisons we may make with regard to the circumstances in which we live we have no right to be especially proud of ourselves. I do not know that medical men have now greater interest in their science, greater appreciation of their work, or a higher sense of their responsibilities in connexion with it than they formerly had. I do not think that we are justified in asserting, as has been recently done, that "an almost entire transformation in surgical ideals has occurred," or

Digitized by Google

that there has been "a wonderful unfolding, enlarging, ennobling of the thought, spirit, aim, and ideal of surgery." So far as I can judge, the spirit, aim, and ideal of the seniors in my early life were as high and as noble as those of my juniors at the present time. They would have hailed with as much pleasure, and with the same motive, as is now done the increased means afforded for doing good in their generation.

Examination and education have shared in the general change, we will hope, somewhat for the better. I may be, and it is natural that I should be, *laudator temporis acti*. Certainly I often congratulate myself that my lot was cast in the days before examination tests and subjects of study were so numerous and *régime* so strict; when we were more free and there was little to damp our pleasure in our work. The enormous advantage of pleasure in study is, and must be to some extent, sacrificed to what is, perhaps, the necessity of examination test. I hope the general standard is raised, but I think we are apt to forget that the faculty of acquiring and retaining knowledge does not increase with the increase in the number and range of subjects any more than the power of digestion increases with the increase of food taken. Indeed, both brain and stomach are liable to be weakened by overloading. There is, to my mind, too great a mass of facts heaped on the memory, too little reflection on them inculcated, too great a straining after the directly practical, too little aspiration for the principles upon which good practice must be based, and too little of the kind of teaching which Lawrence and Latham and Brodie gave us. The sciences of physiology and histology have become, and those of pathology and anatomy are becoming, more separated from medicine—delegated, that is, to special teachers and special examiners, greatly, doubtless, to the advantage and width of scope of those sciences and to the greater knowledge of them; but I fear there is hereby engendered a tendency to take the student too far afield, and the remark applies to the so-called preliminary scientific subjects. It is apt to lead too much to meandering in altitudes, too little to steady straight-going upon *terra firma*, too much to pride and obtrusiveness of supposed higher knowledge, too little to reasoning and too little to power of reasoning upon simple data, and too little to that sort of reasoning which constitutes the basis of "common sense." The scientific and the practical, in short, become too much separated, and what is needed is a greater regard to that connexion between the two which should be maintained through the whole period of study. Upon examination methods I will not enter; they have recently been discussed in another place by one singularly qualified to judge. I will merely observe that they should test the qualities of readiness and briskness as well as those of calm, sober thought; for both are of so great importance in the practical work of our profession.

Prophecy is but inference from the knowledge of the past, and what does the past tell us of the future? It tells us that progress is sure to go on—to go on in medicine at about the same rate as in other sciences, but how and in what directions the progress will be made we cannot tell. The future, we may be certain, will differ from the present, but in what the differences will consist is not within our ken. The "blindness to the future kindly given," humiliating though it be, acts as a never-failing stimulus to our energies and our hopes. Great discoveries and great improvements in medicine have rarely been reasoned up to. The science is too difficult for that. They come like lightning flashes and take effect only where fuel is ready to be ignited. They are going on all around us, and it is the business of such societies as this to turn them to account and to photograph them. No one of your meetings takes place without bringing the opportunity for this. Each fact brought before you is a flash to be fixed and to kindle some thought. The facts may seem to be simple, but the inferences from them may be valuable. Any apparent dulness is probably not in ourselves, but in those who do not appreciate them, who, perhaps, have become too much accustomed to them to heed and scrutinise them. An ordinary case of hydrocele—the simplest of diseases—your society would, perhaps, consider to be beneath its notice; yet how little do we really know of it. How comes it and why does it defy all treatment, local and general, except the trocar? How much of physiology and pathology is hidden in it. *Ex hoc uno disce* not to despise simple cases, but to come to your meeting prepared to listen and to think over them as well as to communicate from your own stores, more particularly if you have anything new, or apparently new, to say or suggest about an old thing. Then will you come with pleasure, and profit by the coming.

An Address
ON
THE SURGICAL ASPECT OF TUBERCULOSIS

Delivered at the Opening of the Manchester Medical Society on Oct. 2nd, 1895,

BY FREDERICK TREVES, F.R.C.S. ENG.,
SURGEON TO, AND LECTURER ON SURGERY AT, THE LONDON HOSPITAL; EXAMINER IN SURGERY AT THE UNIVERSITY OF CAMBRIDGE.

GENTLEMEN,—The changes in surgical affairs have within recent periods been so many-sided that it is probably well to pause now and then to review the nature and import of some of these revolutionary phases. Among them not the least interesting is that which concerns the attitude of surgery towards certain common tuberculous lesions. Less than fifty years ago it was assumed that tuberculosis lay beyond the province of the already sufficiently aggressive surgeon. The surgeon was allowed to take a languid interest in a disorder called scrofula, although his powers for good extended little beyond the application of iodine with a paint brush. The laying on of iodine served to replace the laying on of hands which in the seventeenth century gave to kings the privilege of curing this affection by the touch. Scrofula was in every way a convenient disorder. It was a cloak which covered a multitude of pathological sins. It represented something in the blood; it had a whispered relationship to syphilis; there was about it something of the attractive romance which attaches to an obscure domestic scandal. In reality the term stood, like the algebraical *x*, as representative of a profound quantity of ignorance. There was little agreement as to what scrofula really was, except to the extent that it admitted a large factor of the unknown. As soon as the term "tubercle" crept into existence scrofula and tuberculosis began to play the part of two Dromios in a tedious Comedy of Errors. Among the minor benefits which mark the close of the nineteenth century must be placed the discovery which brought this drama to an end. Nothing in the literature of medicine can compare with the great war of words which waged around these two time-worn terms. For more than one hundred years there was no peace in the pathological camp, and no assured period of silence fell upon a turmoil which was never other than wearisome. Hither and thither these two terms were bandied, with infinite vicissitudes and troublous importunity. At one time all the diseased conditions under dispute were ranked as scrofulous, and at another time as tuberculous; while now and then the agnostic of the time would declare that there was no scrofula or no tuberculosis, according to whichever mood suited his parable. Each writer defined the expressions "scrofulous" and "tuberculous" according to his individual lights, and in the resulting confusion of tongues the words had a meaning only to those who used them. One patient author has written the history of this conflict. His work—"The Chronicles of Tuberculosis"[1]—contains much of what little romance belongs to medicine and provides a strange picture of the development of a scientific creed. The work—although concerned mainly with the literature of modern times—includes the expressions of no fewer than 637 writers upon the subject.

It is difficult to avoid the temptation of alluding to a few crises in this great discussion. Scrofula was originally considered to be exemplified by the familiar chronic gland swellings in the neck, and later the term "tuberculous" was assumed to be most suitably applied to phthisis. It will be no matter for wonder that the conspicuous and disfiguring gland disease had a place in the nomenclature of medicine before pulmonary phthisis had been differentiated from among the numerous chronic

[1] Die Geschichte der Tuberkulose. By Dr. August Prédbl. Hamburg, 1888.

Digitized by Google

affections of the chest. To the clinical observer the unwholesome-looking child with his swollen neck had become a clear individuality while yet the great world of pulmonary disease was without form and void. The χοιράδες of Hippocrates was rendered into Latin as scrofulæ, and the word in due course became English. Hippocrates and Galen considered scrofula to be due to a cold and pituitous condition of the humours, and this pretty fancy, this baseless fabric of a disease, remained an item of scientific knowledge for many centuries. Throughout the voluminous history of the seventeenth century this conception of scrofula still flourished, and there were few who did not cling to the gospel of the pituitous humour. Some, like the great Wiseman,[2] were led away by a belief in a peculiar acidity or acrimony of the blood, but the majority clung to the old faith. In the sixteenth and seventeenth centuries scrofula was, according to the views of the time, a widely prevalent affection. It was popularly spoken of as "the evil," and it stood forth as one of the great scourges of the day. Tuberculosis had not yet appeared upon the scene, and the term "tuberculous," when it was first employed, had about the same anatomical meaning as the term "nodular."

The increasing study of pathology led to a fuller knowledge of the post-mortem appearances in pulmonary phthisis, and then followed the first great event in the history of tuberculosis. About 1679 it dawned upon Francis Sylvius[3] that there was a resemblance between the changes noticed in phthisical lungs and those which had long been familiar in scrofulous glands. Sylvius went so far as to maintain that the morbid processes involved in the two diseases were the same, and that the tuberculous masses found in the lung were identical with those so often seen in the glands. To give reality to his belief he assumed the existence in the lung of minute lymphatic glands, which became swollen and, in due course, caseous and broken down. Thus, pulmonary phthisis became to be regarded as scrofula of the lung, and for long this theory held good.[4] Tubercles of the lung were soon very generally recognised, and the description of phthisis given by the ingenious Matthew Baillie in 1793 leaves little to be desired.[5] Early in the present century the second great event in the history of tuberculosis was reached. Bayle and Laennec[6] recognised the primary importance of the tubercle, and described with precision its exact anatomical condition. Laennec prepared the way for the recognition of tubercle as a product of parasitic nature. Scrofula was now dethroned and became a mere humble appendage of tuberculosis. The pituitous humour disappeared for ever, and the miliary tubercle reigned in its stead. There then followed an idolatry of the tubercle, which was no whit less fervent than the present worship of the bacillus. Laennec and his followers held up upon the point of a needle a minute grain, smaller than a millet seed, which they had isolated from a phthisical lung, and affirmed that it was the very cause of that dire disease. They claimed to have discovered a pathological element, and to hold on the needle point the secret of a mystery and the veritable seed of a disease. It seemed, indeed, as if the man of science had reached the actual confines of human inquiry, and that beyond the little speck on the needle there was only the unapproachable problem of the universe. There soon followed the third epoch in this changeful history. Buhl,[7] in 1857, ventured to regard miliary tuberculosis as an infective disease due to the absorption of a specific virus, and at once a new diagnostic feature came into being. In 1865 Villemin[8] actually demonstrated the infective nature of tubercle by a series of experiments on animals. In the meanwhile the tubercle had been demonstrated in the whole series of so-called strumous diseases, in the enlarged glands, in the scrofulous ulcer, in lupus, in caries of bone, and in the long familiar "white swelling." Finally, in 1882,[9] Koch published the account of his discovery of the tubercle bacillus. That organism was soon shown to be present in every recognised tuberculous and scrofulous affection, and here for the present the matter rests. In the fable the mountain was moved and a mouse came forth. The great mystery of the miliary tubercle had been shaken, and there issues the bacillus. Once more the student seems to have reached the limit of philosophical inquiry. As for scrofula, that once all-important disease fades, after multitudinous changes of fortune, into non-existence. As a definite disease it has no being, and the term is merely a ghostly relic of the past. Tuberculosis may now be defined as an infective disease in which the tissue changes are due to the action of a specific micro-organism, the tubercle bacillus. These tissue changes are, in their general characteristics, those of an inflammation of a low and usually chronic type. The use of the term "neoplasm" in association with tubercle appears to me to be fallacious and misleading. The inflammatory process concerned with tuberculosis is feeble and insidious—it is prone to extend locally; the troubled area is ill defined in its limits, and there is little tendency to produce a defensive barrier which will isolate the infected region. The products of the process are flimsy and unstable. Caseation is so far common as to be almost characteristic. Repair is uncertain and often insecure, and suppuration offers a quite frequent means of cure. Tuberculous affections respond readily to treatment when a free eradication of the diseased tissue is possible. The existence of extensive caseation has no little influence upon the details of surgical treatment. The process of caseation is one of necrosis and fatty degeneration. Caseous matter is not deposited in the usual pathological sense, and the term "caseous deposit" is misleading. Caseous matter is not inspissated pus, nor is it capable of any other than a merely chemical change. It cannot "break down into pus," as the common expression goes. The cheesy nodule is absolutely incapable of so active a process as pus formation. It is merely a mass of dead material, comparable to the sequestrum in necrosis of bone. Suppuration is often excited in the tissues around it, and the object of such suppuration is obviously to rid the body of the noxious mass. It is cast out as a foreign body is expelled, and its removal by surgical measures serves to restore peace to the disturbed district. The caseous material does not of necessity involve suppuration. It may become inspissated and leathery; it may undergo calcareous change; it may become encysted. As a general surgical proposition it may be said that it is as desirable to rid the body of a caseous mass as it is to remove from it a portion of necrosed bone, although the proposition, when the tuberculous lesion is concerned, is modified by many circumstances.

When one comes to consider the tuberculous individual it is essential to bear in mind that two things are needed to set in action the tuberculous process. There must be the seed and there must be a suitable soil. The seed is provided by the tubercle bacillus, and among the haunts of men this bacillus is, without doubt, liberally distributed. The more closely human beings are packed together the more common may the bacillus be expected to be. In spite of the very general diffusion of the bacterium in our midst, it is remarkable that tuberculosis, although a common affection enough, is by no means common to all men. Some individuals are more exposed to infection than others, but that does not explain the distribution of the disease. Were the seed alone the necessary thing, then all the nurses in hospitals for phthisis should become tuberculous, and from such institutions tuberculosis should spread as from a centre. Tuberculous disease, however, does not spread in this way, or only in a few very rare accidental instances, to which a little too much attention has been paid. It is evident that the soil is of much more importance than the seed—that there must be a large proportion of a population who are practically non-inoculable, while there is a proportion whose bodies form a suitable medium in which the bacillus can grow. The tuberculous individual is the one whose tissues form a suitable soil for the development of the bacillus. The non-tuberculosis individual is the one in whose tissues this micro-organism cannot obtain a hold, it being assumed that both are equally exposed to infection. Tuberculous disease may be acquired, but it cannot be inherited; that is to say, the parent cannot hand down to its offspring the tuberculous process in its complete condition, with its bacilli, its tubercles, and its caseating districts. What the parent can unfortunately transmit to its offspring is a body whose tissues form a suitable soil for the development of the bacillus, should that microbe ever reach it in sufficient strength. What is inherited, as a matter of fact, is not a

disease, but a predisposition. On the other hand, the state of body needed to form a suitable soil for the bacillus may be acquired. This is well seen in what is known as "penitentiary" or "workhouse" tuberculosis. A number of children find their way to these institutions. Their parents may have been entirely free from tuberculosis, although possibly not perfect in health in other respects. These children are often brought up under unhygienic conditions, with insufficient exercise, insufficient sunlight, insufficient air, and insufficient food. Types of the individual thus produced are to be met with in the sodden-looking, purple-faced, clownish children who are now and then seen shuffling their chilled limbs in the ranks of a charity school parade. A small proportion of these depressing creatures become tuberculous for no other reason than that their surroundings during the period of growth have been such as to render their tissues a favourable soil for the bacillus of tubercle.

It has been said by some writers that any condition of ill-health may render a patient disposed to tubercle; but this is not so. The distribution of tuberculosis is not identical with mere ill-health. In connexion with the matter of soil, a prominent place must be given to localising conditions, such as injury in bone and joint disease, and catarrh and ulceration in connexion with tuberculous troubles of the respiratory passages and the alimentary canal. With regard to the question of the transmission of the bacillus or the channels of infection in tuberculosis, convincing evidence on many points is still lacking in regard to the human subject. Experiments upon animals have amply demonstrated the transmission of tubercle: (1) by inoculation, (2) by respiration, (3) by cohabitation, and (4) by feeding. When the possibilities of such transmission in man are studied in the light of clinical experience it soon becomes evident that data derived from laboratory researches and experiments upon animals must be accepted with considerable modification if it be sought to apply them to the disease in man. The animal man, viewed as a corpus vile, does not respond very readily to the tuberculous virus when it is introduced into the body by an unintended experiment. The position, so far as it can be discussed upon clinical data only, may be considered under the four headings just alluded to.

1. *Transmission by inoculation.*—Considering the wide distribution of tuberculous disease, and the fact that in many forms of it a discharge exists in which tubercle bacilli are more or less numerous, it is remarkable how very rare are examples in man of inoculation with tuberculosis through the medium of the skin or mucous membrane. It is evident that to effect such inoculation the circumstances must in one way or another be most exceptional. The pathologist at a large hospital for phthisis must have his hands soaked for hours at a time with tuberculous pus. His knuckles cannot always be free from abrasions and scratches, and yet how very rarely does any development of tubercle occur at the undoubtedly inoculated spot. It is true that at least one form of "anatomists' tubercle" is really tuberculous, but the condition remains quite local and is readily cured. Examples of communication by inoculation are afforded by such cases as the following. A servant maid wounds her finger cleaning a spittoon used by a phthisical patient, and develops a tuberculous ulcer at the site of the wound and tuberculous glands in the axilla. A girl tattooed on the arm by her lover who was dying of phthisis develops lupus at the inoculated spot. Lupus of the pinna has followed the wearing of earrings belonging to a phthisical patient. Tuberculosis has been several times communicated by the Jewish method of circumcision.

(2) *By respiration and* (3) *by cohabitation.*—A certain number of instances have been recorded in which it is more or less apparent that tuberculosis in the form of phthisis was communicated to a sound individual. The examples have been mainly noticed in the persons of husbands and wives, or intimate friends, or nurses and patients. The cases, however, are quite uncommon, considering the wide prevalence of the disease. Jousset would place them as low as 2 per cent. This method of communicating tuberculosis is practically unknown in hospitals for phthisis. On the other hand, it has been made evident that tuberculosis is more common in crowded communities.

(4) *By feeding.*—This method of communicating tubercle is in the human subject exceedingly rare and is doubted by many. Jousset (writing in 1893) affirms that no case has been demonstrated. It would appear that the bacilli of tubercle cannot live in the healthy stomach, and cannot survive the heat involved in the cooking of meat. The communication of the disease to a child by means of milk from a tuberculous cow has not been established beyond doubt. Niepve gives the case of an infant born of healthy parents who was suckled by a tuberculous nurse who had bacilli in her milk; the child soon died of tuberculous meningitis. That tuberculosis, however, is very frequently developed through infection from the mouth is undoubted. This is seen in the common enlargement of the cervical glands in association with some such trifling lesions in the mouth as may afford a convenient entrance for the tubercle bacillus. The steps of the infection from the mucous membrane to the glands have been well demonstrated in cervical gland disease in pigs. On clinical grounds this channel of infection would appear to be very common in the human subject, although it does not prove that the infection is conveyed to the mouth by actual articles of diet, such as milk from a tuberculous cow. It may here be mentioned that it would appear that the tonsils and the circle of adenoid tissue at the commencement of the pharynx form a kind of protective ring to the entrances to the larynx and pharynx. "The mass of adenoid tissue," writes Dr. Sims Woodhead,[10] "whatever its situation, if the cells are active, is a means of protection in so far as it consists of an enormous number of active cells which are capable of taking up large numbers of micro-organisms. ..... So long as these tonsils remain healthy, or so long as they are attacked by no extraordinary number of pathogenic micro-organisms, they are capable of resisting attacks and of dealing with micro-organisms, even of what would be called a most virulent type. ..... In many cases the tonsil itself bears evidence of being effected by tuberculous disease. It is evident that under certain conditions the very structures which ordinarily offer resistance to the general invasion of the bacillus may be so disorganised that they are no longer capable of dealing effectively with the organisms by which they are attacked." Dr. Woodhead proceeds to point out how the cervical glands become infected from these diseased tonsils.

These observations are worthy of being considered. I am frequently told by patients that they have been assured that the tonsils are quite useless organs and that any child is better without them. This statement is generally placed among the arguments advanced for the removal of the body in question. It is impossible to too strongly urge the immediate removal of actually diseased tonsils in unhealthy children, and the eradication of the pharyngeal tissue when it reaches the condition known as "post-nasal growths." At the same time, the wholesale removal of all tonsils which are just large enough to be evident as projections would probably sacrifice not a few masses of adenoid tissue which are still active and still capable of protecting the body from the invasion of noxious germs.

We now come to consider the general treatment of tuberculosis from a surgical standpoint. The first elements in the treatment are plenty of air, plenty of sunshine, and plenty of good food. Let the patient escape from the crowded city and live in the country; let him sleep with his bedroom windows open winter and summer. So long as mere movement will not be in itself injurious, let him be moved into the open air. Let him strive to live in the open air. The atmosphere should be dry. Patients do not do well in densely wooded districts, in valleys by the banks of large rivers, and in moist places. They do better by the sea, in districts with a low rainfall, with a porous soil, with spare vegetation, and with an unimpeded rush of air from the sea. Sunshine and dry air are deadly to the bacillus, and light and oxygen are of more value than all drugs. In the open air the tuberculous patient may feel safe. In England there is some difficulty in spending much time in the open air in the winter, although I have had patients with high temperatures and suppurating wounds, with acute joint mischief and psoas abscesses out of doors every day in the winter in spite of snow and frost and rain. The good results that I have seen to follow the operative treatment of spinal abscess have been due in no small degree to the fact that many of my patients after operation were able to be taken out of doors on a spinal carriage every day and all day through the whole of an English winter.[11] The great feature of Thomas's splints lies in the fact that they permit the patient to move out of the house. If the patient can winter in a more suitable climate than England, let him go to a place where the

Digitized by Google

air is dry and the sun bright, and where he can be out of doors all day. Thus it happens that surgical forms of tuberculosis do as well at St. Moritz and in Canada as at Cairo and California. These are places with this at least in common: there are facilities and inducements to be out of doors in the winter months.

There are no drugs which are specifics against tubercle, and three-fourths of the medicines given are administered, not to treat the disease, but to soothe that inherited craving in the human race for physic, which is almost as uncontrollable as the craving for drink. Tuberculous subjects, especially children, appear to be benefited by taking an extra amount of fatty matter in their food during the cold weather. This can be supplied in the form of fat, butter, or cream. There is no excuse, so far as I am aware, for the administration of cod-liver oil. In all probability there is no more nauseous form of fat to be found, and I am not aware that it contains any chemical quality other than that of oil. Its use dates from a time when it was considered in keeping with the fitness of things that all medicines should be nasty. If adults like this oil, by all means let them take it; but it is unkind to force it upon children, who have no prejudices as to the efficacy of medicine, and have not reached an age to appreciate the beauty of nastiness. The public, moreover, cling to the belief that there are such medicines as "tonics." Tonics are medicines which give the taker strength. It is needless to say that there are no medicines which can effect this. Strength cannot be poured down the œsophagus. One might as well add to the Pharmacopœia a physic the taking of which will give wealth. Iron may be needed when there is anæmia, and is conveniently given to children in the form of Flitwick water. Arsenic and quinine are now and then of value, and in some few instances iodide of potassium is of service. Iodine is constantly employed in the form of Kreuznach water, and the special treatment carried out at Kreuznach is often of decided benefit in the early stages of gland disease.

With regard to the local or surgical treatment of tuberculous affections, it is interesting to note the changes which have taken place, and which are still taking place, in connexion with this department of practice. The time is not very far distant when tuberculous or scrofulous troubles were considered to be unsuited for surgical treatment. They were regarded as "constitutional" disorders, and as such were presumed to belong to the province of the physician. The surgeon applied splints, blisters, and iodine, and occasionally opened an abscess and removed a long-dead fragment of bone, but the responsibility of serious treatment rested with the man of medicine. Then came the great surgical revival, and tuberculous affections were attacked in common with nearly all other disorders which presented any local manifestations. There is no doubt but that in a while the pendulum swung too far in the opposite direction. From the position of not treating tuberculous affections at all, it proved to be a short step to the position of treating them too much. Now, I think, the mean is being arrived at, and the surgical treatment of tuberculous affections is becoming free of extremes. This is strikingly illustrated in connexion with the care of tuberculous joints, such as the hip and knee. The first care is to place the patient under what the student in his examination paper delights to call "favourable hygienic conditions." I am quite aware that among poor patients this is not always possible. Then the joint is placed scientifically at rest. The thigh—if the disease lie at the hip—is not abruptly forced into a stereotyped position which the surgeon declares to be one of rest, but which in reality is one of discomfort and one in which the tension within the joint is increased. The limb, on the contrary, is gently induced into the natural position and kept there. Under the treatment by perfect rest, in as nearly as possible perfect conditions, the majority of cases of tuberculous joint disease get well. By so much as the surroundings are imperfect, by so much is that majority reduced. If an abscess form in connexion with the hip, and if that abscess be treated upon general surgical principles, again it may be said that the majority get well. As an evidence of this, must be cited joint disease among the better classes. This is a very different story from the one told but a few years ago. It was assumed that the majority of cases of joint disease went from bad to worse. There was some truth in the assumption, and amputations were common. Excisions, mainly of the knee, were commoner. Mr. Holmes, writing in 1880, gives the results of 245 cases of excision of the knee performed in certain hospitals in London during five years. It would be interesting to know how many excisions of the knee for active tuberculous disease are performed in London per annum at the present time. A distinguished surgeon, writing in 1892, states that "when a well-marked case of pulpy disease has lasted over six months it is not worth while, in the interests of the patient, to attempt the conservation of the joint for a longer period." This was written in connexion with excision of the knee. There was a time, not so many years ago, when, in the opinion of some surgeons, excision of the hip or knee should be performed as soon as the diagnosis of tuberculous disease was established. Even by this time so-called "primary excisions" are more or less matters of the past. It was furthermore urged in connexion with hip-joint disease that as soon as an abscess appeared an excision should be carried out. It would, I think, be safe to predict that that verdict will not be confirmed in the immediate future. The excellent operation of arthrectomy, for the elaboration of which surgery is largely indebted to Mr. Wright of Manchester, is becoming wisely restricted in its use. Instead of being more frequently employed it is less frequently employed, and it has become quite manifest that it is not adapted as a routine treatment for even one particular phase of joint disease. Mr. Howard Marsh, in his recent work on "Diseases of the Joints," gives an excellent review of the present position of surgical feeling upon this subject, and in contrast to the literature of the time when excision (or, later on, arthrectomy) was almost a routine measure, his account shows a singular change in surgical practice.

In the treatment of tuberculous gland disease there was a great leap from doing nothing to doing possibly to much. The treatment of tuberculous glands of a certain grade by complete excision is in every way most excellent, and has been attended with the best results. But here, again, there is evidence that is is possible in adopting a new measure of treatment to run into extremes. It has been assumed by not a few that the only treatment of tuberculous glands is by excision, and I have heard the claim advanced that as soon as it is evident that a gland is tuberculous it must be removed. Those who urge this claim assert that there is no other course open and that disaster will follow if an operation be not at once performed. This pressing of an admirable measure to an extreme and irrational use is tending to bring a most useful operation into discredit. It may be safely asserted that certain cases of tuberculous gland disease recover, and recover well, without operation; and, also, that there are instances of gland trouble, especially when extensive and in adults, which are not suited for operation. In the treatment of gland disease two matters call for early attention. In the first place, it is essential that the periphery be examined and any exciting cause be dealt with as a primary feature in the treatment. There may be discovered some eczema of the scalp, or some discharge from the ear, or some nasal catarrh. In many instances there are enlarged tonsils, or post-nasal growths, or some ulceration within the mouth, or some wholly carious teeth. It is of little avail to attempt to treat tuberculous glands when the tonsil from which they have been infected is left untouched. I can recall the case of a young patient with enlarged cervical glands, who had been sent to certain well-esteemed health resorts without benefit, and who was finally advised to have the glands removed as the only measure of cure possible. The glands depended upon a tuberculous ulceration of the tongue, and when the tongue was treated and healed the glands subsided and ceased to give trouble. Many like cases may be quoted. As a second element in the treatment the part must be kept at rest. This is generally insisted upon when the enlarged glands occupy the axilla or the groin, but it is seldom urged when the trouble is in the neck. Yet the neck is in almost constant movement, and when the glands are beneath the sterno-mastoid muscle they are subjected to continual disturbance. Until the neck is fixed the great essential in the treatment of inflamed parts is ignored. In very many cases there is no measure for the diseased glands but removal, but this measure is likely to fall into disrepute if it become an article of faith—as it is with some—that the only treatment of a tuberculous gland is by immediate operation. It is sometimes promised to the patient that the scar left by the operation upon the glands will be quite insignificant, and, indeed, a mere white line, which will compare in a startling manner with the hideous scars left by "nature." Surgeons, on the other hand, who have seen much of the operations, will not be disposed to lay too much stress upon the invariable fineness and invisibility of the cicatrix left by art.

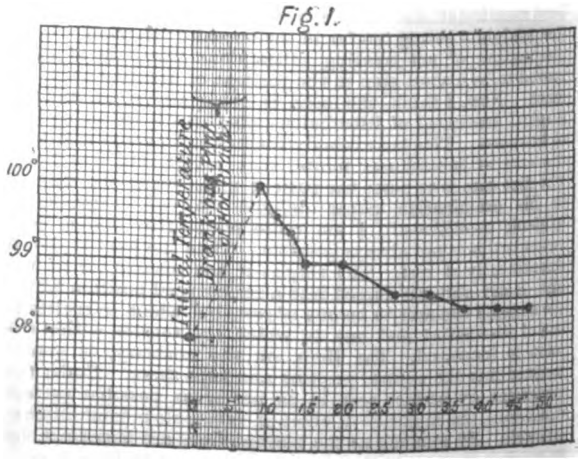
When we turn to the treatment of tuberculous testis, it will be found that the fashions in treatment have followed some such lines as the following: In the early days the trouble was condemned as "constitutional," and left alone. Later the testicle was removed when it and the scrotum were hopelessly disorganised; it was evident that these operations were done too late. And then came the advice that the whole organ should be excised as soon as suppuration made itself evident; many of these operations were certainly too early. Now, perhaps, something like the right mean has been arrived at. The patient is placed under as favourable conditions as are possible, and the moment any point of softening appears in the epididymis, it is well opened up, well scraped, and well plugged with iodoform gauze. The operation may have to be repeated more than once. What is the result of this measure? In common with many other surgeons, I can cite an encouraging series of cases in which this simple plan of treatment has led to a complete cure, with loss of substance no doubt, but without loss of the essential part of the organ. It is, however, in connexion with the treatment of spinal and other tuberculous abscesses that the contrast between the treatment of the past and the present is the most striking in its results.

Not many years ago a psoas abscess was rightly considered to be a very fatal thing. The abscess usually presented below Poupart's ligament, and was allowed to break or was opened in a faint-hearted manner. Then followed the disastrous train of results due to inadequate evacuation of the morbid products, inadequate drainage, want of suitable rest to the parts, and the inevitable introduction of sepsis. The majority of the patients died, and among adults especially the results were most deplorable. At the present time the position of affairs is much altered. The actual steps of the operative treatment differ a little with different surgeons. The proceeding I have adopted myself is the following. The abscess is reached through the loin by the route I ventured to advocate in a paper read before the Royal Medical and Chirurgical Society in January, 1884. By this incision the abscess is opened as near as possible to the seat of disease. The spine, over a limited area, can be examined, and now and then diseased bone can be removed. The largest sequestrum I ever removed involved the greater part of the body of the first lumbar vertebra. Cases associated with such large sequestra are, however, quite rare. Now and then a surface of carious bone can be scraped. When the abscess has been evacuated suitable sharp spoons are introduced, and the lining wall of the cavity is carefully and thoroughly scraped until the whole surface has been laid bare. During the process the cavity is repeatedly flushed out with warm sterilised water, which, at the London Hospital, comes direct from a Berkfeld filter. Septa are broken down with the fingers and diverticula opened up. The amount of pus, cheesy matter, and membrane removed is often surprising. When the cavity is clean it is well dried with Turkey sponges on holders, which serves to remove what remains of débris. Finally, a little iodoform emulsion is introduced and the wound then closed. In spite of the contradictory evidence furnished by laboratory experiments, it certainly does appear, from clinical observation, that iodoform has a specific effect upon tuberculous lesions. The well-to-do patient passes his convalescence on a spinal carriage in the open air, be it winter or summer. The cavity left by the operation is more like that left by the removal of a very large tumour, such as a lipoma. It does not behave as does the wall of an ordinary septic abscess, and the healing is very usually immediate and complete. This peculiarity in the inflammatory phenomena with which tuberculosis is associated is well illustrated by the manner in which tuberculous peritonitis responds to operative treatment. In a series of 308 cases of tuberculous peritonitis treated by laparotomy there were 74 deaths, the mortality due directly to the operation being only 2·5 per cent. Those cases did best in which the operation consisted of little more than a free incision, and in which there was neither flushing of the abdominal cavity nor drainage. I think it may be said that in no non-tuberculous inflammatory condition is a parallel to this to be met with.

Such, in very brief and imperfect outline, are some of the changes which have in recent years concerned the relation of the surgeon to tuberculous disease. These changes have taken place along leisurely lines, and have been so far free from abrupt and startling departures that it is only when they are passed in review that the magnitude of their meaning is made evident. I think it may be affirmed that the lead in this department of progress has been taken by the surgeons of this country, and that this progress has been marked by that discriminating common-sense which has always been conspicuous in British surgery.



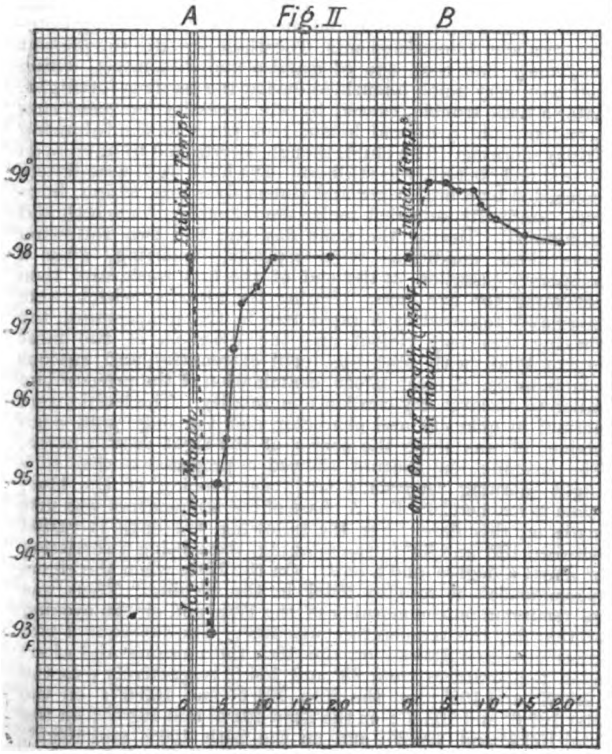
Wimpole-street, W.

ON THE VARIATIONS IN THE TEMPERATURE OF THE MOUTH IN HEALTH PRODUCED BY LOCAL APPLICATION OF HEAT AND COLD.

BY W. S. LAZARUS-BARLOW, M.D., M.R.C.P. LOND.,
DEMONSTRATOR OF PATHOLOGY IN THE UNIVERSITY OF CAMBRIDGE.

BY reason of accessibility and a belief that the true body temperature is thereby more nearly obtained it has become very usual to take the temperature of patients by placing the clinical thermometer in the mouth, while at the same time the patient is directed to keep the bulb under his tongue and his lips firmly closed around the stem of the instrument. This site has largely taken the place of the axilla, particularly in the case of patients who are fully dressed. The following simple experiment, however, will show that considerable care must be exercised before concluding that the mouth temperature is an indicator of the body temperature—if, indeed, it be not entirely deceptive. If an ordinary healthy person take the mouth temperature and then drink some moderately hot fluid, such as a cup of tea, and on finishing it again take his temperature in the same situation, he will find that the thermometer now registers one or two degrees more than it did at first. The importance of this fact, which can easily be verified, led to my undertaking certain experiments upon the subject with a view to determining the conditions under which the temperature in the mouth varies. An adult male perfectly healthy, but confined to bed by a small surgical ailment, was made the chief subject of the experiments. His temperature was normal, and the experiments were for the most part made about 2 P.M. It is unnecessary to give more than one example in each class of experiment, by reason of the uniformity of the results.

1. *The effect of heat locally applied by means of hot drinks.*—Below is given a typical temperature curve (Fig. 1) where the subject of the experiment took one pint of beef-tea the temperature of which varied between 150° F. and 110° during the time of its consumption. It will be noticed that (*a*) the

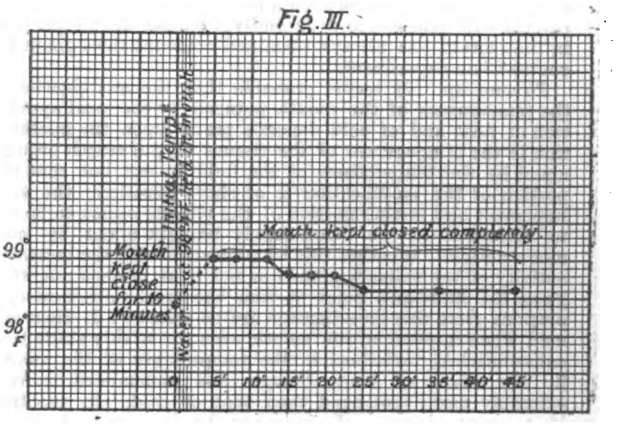


To show the effect of hot fluid upon the temperature of the mouth.

highest point of the rise occurs immediately after the fluid has been taken and that the temperature falls somewhat rapidly at first, but more slowly afterwards; and (*b*) the temperature in the mouth is still raised 0·4° forty minutes after the fluid has completely left the mouth.

2. *A comparison between the effects of heat and cold.*—The effect of cold applied by means of fluid at 50° was separately examined, but it will conduce to brevity if that set of

Digitized by Google



experiments be merged in the present class. The difference between them is merely one of degree. In order more accurately to compare the effects of heat and cold the period during which either was allowed to act upon the mouth was fixed at one minute. For a reason which will immediately appear the action of cold was invariably investigated before that of heat. The method of experiment was as follows. The temperature in the mouth was first taken with great care. A piece of ice of sufficient size to ensure that some was unmelted at the end of the allotted time was then kept in the mouth for one minute; the temperatures obtained from time to time afterwards were compared with the initial temperature. After the mouth temperature had again reached the initial temperature and had remained constant for a quarter of an hour, half an ounce of broth at 140° was held in the mouth, also for one minute, and the temperatures were registered as before. Below is a typical curve of such a double experiment. (Fig. 2.) It must be

To show the effects of holding (A) ice and (B) fluid at 140° F. in the mouth, each for one minute. Note.—B was not commenced till a quarter of an hour after the temperature change brought about in A had become readjusted.

borne in mind that the difference from the body temperature in the two experiments A and B was not the same, being 66° (98°–32°) in the case of the ice, and but 42° (140°–98°) in the case of the broth. In accordance with the greater temperature difference in the case of the ice the initial fall of the mouth temperature is greater, but, contrary to all expectation, the recovery is much more rapid than in the case of the hot fluid. Thus, in the example given above, the return to normal in the case of ice was complete in ten minutes, whereas with the hot fluid the rise, though less marked, was more prolonged, so that at the end of ten minutes the temperature of the mouth was still half a degree higher than it was before the broth was taken, while it was still above the initial temperature at the end of twenty minutes. The more rapid recovery of the mouth temperature from cold in such experiments as the above has been found to be invariable. The effect of cold, however, is not only shown when cold liquids or solids are taken, but it is also shown when cold air is inspired through the mouth. Thus, when a healthy person with an initial temperature of 97·6° (taken with the mouth closed for ten minutes) breathed through the open mouth air at 30° for forty-five seconds, drawing during that time twenty full breaths, his mouth temperature was, three minutes later, 96·8° (a fall of 0·8°), while it did not again reach the initial height until he had kept the mouth shut for a further seven minutes, making the whole duration of the effect of the cold air ten minutes.[1] It must be remembered, too, in this case that the effect of the cold air upon the mouth in inspiration is partially neutralised by the air at the body temperature which passes over the same parts in expiration. This point is of some importance, since it must be an almost constant source of error, as the temperature of the air respired by any person must vary between very wide limits unless he be definitely confined to a room which is kept at a constant temperature. The extreme variability of the mouth temperature, however, can be shown by even smaller temperature changes than those given above, for I have found that the mere act of reading aloud in an ordinary manner for one minute is sufficient to reduce the mouth temperature 0·3°, while the effect is not completely recovered from until the mouth has been kept closed during the five minutes which elapse after the reading aloud has ceased. The mere act, therefore, of describing his symptoms to the physician lowers appreciably a patient's mouth temperature.

3. *The effect of liquid at the same temperature as the initial temperature of the mouth.*—If the mouth temperature be taken with care, and water heated to the same temperature be held in the mouth for two minutes, the temperature of the mouth rises to a perceptible degree. By reason of the unexpectedness of this result the experiment was repeated many times on different subjects, but always with the same result. In some of the later experiments, since it was possible that even with great care the liquid might have a slightly higher temperature than the mouth, it was not taken into the mouth until it was definitely (half a degree) *below* that of the mouth. This modification, however, did not cause any alteration in the final result. Below is given a typical temperature curve of such an experiment. It will be noticed

To show the effect on the temperature of the mouth of the local application for two minutes of water heated to that temperature.

that by these means a rise of 0·6° is brought about, a rise quite outside the possibility of experimental error. The effect, moreover, is of long duration, since the temperature of the mouth was still raised perceptibly (0·2°) three-quarters of an hour after the water had been swallowed.

The facts, then, being such as have been described, their explanation becomes a matter of interest. That the explanation which first suggests itself—namely, that the modifications depend simply upon a transference of heat from the material with the higher temperature to that with the lower, with the object of equalising the temperatures of both—is not a fully satisfactory one is shown by the experiments of which Fig. 3 is an example. According to this view, since heat was neither added to nor abstracted from the mouth with the liquid, the mouth temperature should remain constant; that it does not so remain constant indicates that

[1] Throughout the whole investigation a "one minute" clinical thermometer was used, and three minutes' duration in the mouth was taken to ensure an accurate reading. The *initial* temperature was obtained invariably by keeping the thermometer in the mouth for ten minutes. For temperatures below 95° a non-registering thermometer was used, but was replaced by the clinical thermometer so soon as the temperature reached 95°.

Digitized by Google

the process is more complicated. Nevertheless, the fact that the rise of the temperature of the mouth varies within limits according to the temperature of the fluid held in the mouth indicates that this explanation probably holds good in part. I would suggest that that portion of the rise or fall (as the case may be) which obtains immediately after the action of the heat or cold has ceased, and which is rapidly obliterated, should be regarded as in part depending upon an actual physical heating or cooling of the actual tissues of the mouth, and particularly the epithelium. Nevertheless, this accounts for a small portion only of the change and leaves entirely unexplained the experiments shown in Fig. 3. Now the simplest way in which these experiments can be explained is by regarding the presence of the water as a stimulus which inhibits the vaso-constrictors of the vessels of the mouth and therefore allows the parts to be flushed with a more rapid stream of blood which has come with less delay and in larger quantities from the deeper parts, and which is, therefore, of a higher temperature than that of the surface. That this is true is suggested by the facts (*a*) that the mouth temperature cannot be indefinitely raised by raising the temperature of the ingested fluids, (*b*) that the temperature change is brought about by a very short application of the stimulus, and (*c*) that it lasts a length of time quite out of proportion to the duration of the stimulus. Since the ingestion of food is accompanied by increased action of the salivary glands it seems reasonable to suppose that the increased temperature of the mouth may be bound up with the arterial congestion which is known to accompany increased salivary secretion. Nevertheless, I have not found that such fluids as clove-water, which markedly increase the secretion of saliva, cause the temperature of the mouth to be raised to any greater extent than does distilled water (at the same temperature), by which the salivary secretion is increased to a much smaller extent. That the modified temperature is not due to a modification of the temperature of the whole blood is obvious—firstly, because such a result is impossible for purely calorimetric reasons, and, secondly, because the temperature in the rectum has always remained constant throughout the course of an experiment.

To sum up. It seems probable that the modification in the temperature of the mouth induced by the local application of heat and of cold depends partly upon the modification in the temperature of the tissues of the mouth brought about by the temperature of the fluid in use, but that this portion of the modification is of short duration; the more important and lasting portion of the change seems to be due to variations in the blood-supply brought about by vaso-motor action. Whether this be connected with the increased activity of the salivary glands or not is at present doubtful. From the clinician's point of view the most important conclusions from this investigation are as follows: 1. Heat and cold when applied to the mouth even for a very short time cause marked variations in the temperature of the mouth. 2. The effect of heat, though less pronounced, is considerably more prolonged than that of cold. In practice, if a great degree of accuracy be required, I would suggest that the temperature should never be taken in the mouth unless other parts are inaccessible; but, if only the mouth be available, then attention should be paid to the following points: (*a*) one hour at least must have elapsed since the last food or drink of any kind, and even in the smallest quantity, has been taken by the patient; and (*b*) for ten minutes previously to inserting the clinical thermometer the mouth must have been kept completely closed. Under such circumstances as these, and under them alone, is a temperature taken in the mouth a reliable index to the body temperature.

Pathological Laboratory, Cambridge.

PATHOLOGICAL SOCIETY OF MANCHESTER.—The annual meeting of this society was held at the Owens College Medical School on Oct. 9th, Professor Sheridan Delépine, President, being in the chair, and the following officers were elected for the session 1895–96:—President: H. R. Hutton, M.B. Vice-Presidents: T. Harris, M.D., and W. Thorburn, F.R.C.S. Treasurer: T. N. Kelynack, M.D. Secretary: R. B. Wild, M.D. Committee: A. Brown, M.D., T. A. Goodfellow, M.D., A. T. Helme, M.D., E. T. Milner, M.B., E. S. Reynolds, M.D., W. P. Stocks, F.R.C.S., A. T. Wilkinson, M.D., and J. B. Wolstenholme, F.R.C.V.S. Auditors: D. Headridge, L.D.S., and J. W. Smith, F.R.C.S.

TWO CASES OF INFECTIVE FEVER SHOWING THE THERAPEUTIC VALUE OF INTESTINAL ANTISEPSIS.

BY LEONARD WILLIAMS, M.B., C.M. GLASG.,
HONORARY MEDICAL OFFICER, SIDMOUTH COTTAGE HOSPITAL.

THE treatment of infective fevers, and of typhoid fever especially, by internal antiseptics has recently been widely advocated. As a contribution to the subject I desire to record two cases—one of an obscure infective fever which I believe to have been typhoid fever, and the other a case of undoubted typhoid fever—both of which were treated by measures calculated to promote intestinal antisepsis.

CASE 1.—I visited a patient on Tuesday, Feb. 5th, 1895, who was threatening to miscarry at the seventh month. She had already borne six children, and there had been nothing noteworthy about the confinements. The whole period of the present pregnancy had been one of malaise and discomfort, which had been very much intensified during the previous fortnight. After a little trouble, caused by the necessity for rectifying a malposition, a normal labour took place on the following Friday morning. The child, though ascertained to have been alive shortly before, was stillborn. The birth was immediately succeeded by a brisk rigor and violent dyspnœa, which, however, gradually subsided under the influence of warmth and stimulants. During the same day and the two following days these conditions were repeated, recurring, after a temporary cessation, at the end of the first week, and then persisting for five days. During the attacks, which were invariably followed by a rapid rise in the temperature, the shaking was very violent and the dyspnœa of the most urgent kind, with blue lips, cold extremities, and anxious countenance. A most careful examination of the præcordium failed to discover any cardiac abnormality. The lochia were normal in quantity and character, and the only pain complained of was along the course of the right sciatic nerve. The evening temperature showed a progressive rise with slight morning remissions until the evening of the 11th, when it reached 103° F. A chart of the temperature was first made on this date. For the following five days it varied between 102° and 99° in the morning, there being a remission of about a degree and a half. On the 16th, when the rigors recommenced, it rose to 104·4° in the evening. There was no remission on the morning of the 17th, and on the evening of that day the temperature was 105°. The subsequent progress was as follows: on the 18th the morning and afternoon temperatures were 99° and 104·6° respectively; on the 19th 99° and 103°; on the 20th 101·6° and 102·6°; on the 21st 101·6° and 102·4°; on the 22nd 101·4° and 102·4°; on the 23rd 100·4° and 102·2°; and on the 24th 100·2° and 102·0°. After this there was a progressive fall until March 1st, when the temperature was normal. The evening temperatures then began gradually to ascend, with decided morning remissions, until the 6th, when 103·6° was once more registered. The temperature, however, very soon fell again, and the case proceeded to a satisfactory issue. I have given the history of the temperature by itself to avoid needless repetition. At the commencement of the disease the cause of the obviously grave state of matters was a source of the greatest anxiety and perplexity. There was at no time any local or other condition tending to give colour to the idea of puerperal septicæmia which was constantly present. The lochia remained normal, and there was no tenderness over the uterus. The diet during the first week consisted of meat broths and jellies, egg-and-milk, and some alcohol. On Feb. 17th I had an opportunity of observing the effect of a meal consisting of some chicken jelly, a little toast, and half an ounce of champagne. It was taken with relish, but was immediately succeeded by flushing of the face and a feeling of discomfort which was shortly followed by a rigor. I therefore concluded that the cause of the rigors was somewhere in the intestinal tract. The food was changed to peptonised milk, with prepared food occasionally. The bowels, which had throughout been confined, had so far been regulated by cascara palatinoids. For these an enema every second day was now substituted. On the 19th Dr. Bankart of Exeter saw the patient with me. He agreed that the diagnosis was very obscure, and had no alteration to suggest in the measures which were being taken beyond a proposal that some general antiseptic

Digitized by Google

should be administered by the mouth, in addition to bismuth, which was being given. I accordingly prescribed carbolic acid in pill form (two and a half grains three times daily). Constipation had all along been a very troublesome factor. The effect of the enemata was sometimes satisfactory, but very often not so. The motions were scybalous and blackened by the bismuth. On the 21st the patient was put upon barley water and milk exclusively and the bismuth was suspended, the carbolic acid pills being continued. As these appeared to produce unpleasant symptoms they were on the 24th also suspended, and thymol in pill form (two grains every three hours) substituted. The brief account of the temperature shows that from this time the patient's condition rapidly improved until March 3rd, when there was an acute recrudescence of the fever. I then determined to prescribe calomel. This was given in doses of two grains on two successive evenings (March 7th and 8th) with the best results, after which the patient made a good though protracted recovery. This rapid survey gives but a slight idea of the difficulties and anxieties of the case. Neuralgia, especially of the fifth and sciatic nerves, was the source of great trouble to the patient. The right parotid gland was swollen and indurated. There were several small oval ulcers on the uvula and back of the pharynx, which caused pain and difficulty in swallowing. Flatulence, abdominal pains and tenderness were very pronounced in the third week. The diagnosis of typhoid fever was not made until Feb. 22nd. The occurrence of the labour, the constant rigors, and the absence of any definite abdominal symptoms all tended to obscure the issue. What is particularly worthy of notice is the marked improvement in the temperature which ensued upon the exhibition, first, of the carbolic acid on the 20th, and, secondly, to a much greater degree, of the thymol on the 24th. The beneficial effects of the calomel administered on March 7th and 8th were probably due chiefly to its antiseptic properties.

CASE 2.—A young man aged nineteen years was taken ill on April 12th. I saw him on the following day and found a temperature of 104·4°F. The tongue was thickly furred, and there had been considerable epistaxis. There was pain in the head and in the right iliac fossa, slight pressure in which elicited gurgling. The general condition was such as to make it evident that the patient would have a very severe attack. He was at once put upon a rigid milk diet, with some alcohol, and was given the quinine and chlorine mixture recommended by Dr. Burney Yeo.[1] For the next four days the patient did not improve, but developed the usual evidences of the typhoid state. The tongue became dry and sordes appeared on the lips and teeth. The abdomen became tense and swollen. He lay on his back with his knees drawn up and tended to slip down in the bed, and his intellect became clouded. The afternoon temperature remained at 104°. On the 18th my friend Dr. Macindoe saw the patient with me. The temperature had fallen to 103·4°, but from his general condition we agreed that the prognosis was of the gravest. No alteration was made in the treatment, a careful pursuance of which we were agreeably surprised to find was soon followed by marked improvement. His afternoon temperatures for the next three days showed a steady decline; they were on the 19th 102·2°, on the 20th 100·6°, and on the 21st 98°. The fall in the temperature was accompanied by a corresponding improvement in the other symptoms, and he made a quick and uninterrupted recovery. I thought at first that there had been some mistake and that the patient was beginning the third week of the disease when I first saw him. This view was very strongly insisted upon by my friend when informed of the progress of the case. All the evidence, however, is against this supposition. The patient himself declares that, except for a slight cold, he was perfectly well until April 12th, and that on the 10th he was playing cricket with enjoyment. During the course of the fever the bowels acted freely, but there was no diarrhœa. The first motion which I saw was characteristic in appearance and odour. In all those shown to me subsequently the fetor was greatly reduced, and towards the end of the attack there was a distinct odour of chlorine in the evacuations. The illness began with every appearance of a very severe attack and the probability of a rapidly fatal issue. There was very little in the patient's favour. He was a delicate lad, the house he was in was insanitary, and he was without a skilled nurse. Yet so early as the end of the first week the case was in the highest degree hopeful, and it progressed with amazing rapidity to a satisfactory issue. This I can only attribute to the line of treatment adopted, and I have no hesitation in saying that, but for my good fortune in reading Dr. Burney Yeo's book, this lad would probably have lost his life.

The solution recommended by Dr. Burney Yeo he directs to be made as follows: "Into a twelve-ounce bottle put thirty grains of potassic chlorate, and pour on this sixty minims of strong HCl. A greenish-yellow gas is at once liberated. Close the bottle with a cork and agitate the mixture gently until the bottle is filled with gas; then pour water into the bottle little by little, closing the bottle and shaking well at each addition, until the bottle is half filled. Add to this mixture from twenty-four to thirty-six grains of quinine, and then fill the bottle with water. The dose is an ounce, administered, according to the severity of the case, every hour to every four hours." The "predominant partner" in the mixture, it seems to me, is the chlorine. It has long been used as a powerful antiseptic, especially as a wash for ulcers; but its special application to typhoid fever is a recent introduction of quite unusual promise. The foregoing cases, both of them severe, were successfully treated by means of intestinal antiseptics. The drugs used differed in the two cases, having, nevertheless, two properties in common. One of these—the germicidal—has already been referred to; the other is the property of volatility, to which I am inclined to attribute much of their efficacy, and I should, in selecting a drug for producing intestinal antisepsis, invariably give the preference to one possessed of this quality. That Case 2 was aborted by the administration of the chlorine mixture I have not the shadow of a doubt, nor have I any hesitation in saying that, but for the exhibition of some antiseptic such as thymol, the patient in Case 1 would not have recovered. The other lines of treatment which were open to me in conducting these cases were the expectant method and the cold bath treatment. The first, necessary as it frequently is in many obscure cases, is obviously a confession either of ignorance or impotence. The cold bath treatment, though it has had many eminent advocates, is one which has failed to find general acceptance. This has been partly due to the fact that it is cumbersome to the point of being dangerous, and largely to the fact that it is unscientific, in that it is a weapon directed against one symptom only, leaving altogether out of account the causation and essential lesions of the disease. The antiseptic method, on the other hand, presents a rational system of treatment directed towards counteracting or minimising the effects of specific morbid activities; it is easy of administration even in the humblest homes and is absolutely free from danger. Those who have had any experience of it will heartily concur with Dr. Burney Yeo when he says that "the practitioner who, in the face of the evidence which has recently been accumulated, neglects to promote intestinal antisepsis in typhoid incurs a very grave responsibility."

Sidmouth.

TROPICAL ABSCESS, RARELY A PRIMARY, USUALLY A SECONDARY, AFFECTION OF THE LIVER.

BY NEIL MACLEOD, M.D. EDIN.

EVERY physician who has had experience of tropical liver abscesses would say that their association with affections of the large bowel is only an occasional one, on clinical grounds alone. Unanimity of opinion on this point ceases if the results of post-mortem examinations are taken into account. Probably a large majority of observers in India hold the opinion of Murchison, which as lately as last year is set forth by Sir Joseph Fayrer in the work "Hygiene and Diseases of Warm Climates," and supported in the same volume by Professor Cayley of Netley—the opinion, namely, that these abscesses are usually the result of a primary suppurative hepatitis. Their origin as secondary to affections of the large gut, enunciated by Budd, Moxon, Martin, and others, is favoured by a minority of observers—a minority lately on the increase. This is a question which cannot be decided by general impressions, but by appeal to recorded cases. If they are usually the result of

Digitized by Google

a primary liver disease, an examination of recorded cases ought to furnish at least a fair proportion in which no lesion was found in the large gut. If, on the other hand, they are rarely primary and usually secondary to a lesion of the intestine, a majority of recorded cases ought to present traces of these intestinal lesions. The following cases ought obviously to be rejected as throwing no light on this question: (*a*) all cases of abscess that have recovered and in which there is no history of bowel affection stated or implied, since post-mortem examination of fatal cases frequently demonstrates the presence of ulcers in the large gut even where dysentery or diarrhœa is stated not to have been present during life; (*b*) for the same reason all fatal cases with a similar negative history not examined after death; and (*c*) fatal cases examined after death, but where no statement is made of the condition of the large bowel—here obviously it cannot be assumed that intestinal lesions were either absent or present. Disregard of these considerations and too close reliance on the clinical aspect of these cases have no doubt led astray many of those who have had to deal with this disease in the East. Commencing my acquaintance with so-called "tropical" liver abscess in the prevailing belief that it was only occasionally associated with the dysenteric lesion, my attention was first pointedly directed fifteen years ago to the question when a case of multiple abscess presented itself not associated with a history of dysentery, but in which cicatrices were found in the large gut after death. Repetition of this experience also with single abscesses, cicatrices or ulcers being found, naturally led me to look with suspicion on recorded statements of the absence of dysenteric history. An experience of about forty cases, every one of which, with one exception, was associated with history of post-mortem signs of dysentery, surely justifies the opinion that the relationship is not one of coincidence merely. The exception recovered. Sir Joseph Fayrer distinguishes four forms of liver abscess which appear to differ from each other only in their etiology.[1] They are: (1) large, generally single abscesses, caused by climatic conditions combined with certain conditions of living, food, and drink, *not associated with dysentery;* (2) those multiple abscesses *secondary to dysenteric ulceration*, with which are classed those occurring "in a person who is or has recently been suffering from fever ..... with Peyerian ulceration" (so far from regarding typhoid ulceration, as it is here stated to be, as a satisfactory cause for these abscesses, the very rarity of such an association - for I cannot find such a case on record—seems to me to throw some light on the question, as I shall try to show later); (3) those abscesses *coincident with, not caused by, dysentery*, malarial fever, and hepatitis, but all of these the result of climatic influences (why is the association with dysentery in the second form regarded as something more than coincidence, but not so in the third?—the third form is said to be "obviously different from the before mentioned," but no obvious difference is furnished); and (4) pyæmic abscesses in any climate secondary to "injury, ulceration of stomach, gall-bladder or duct, gall-stones, ulceration in other parts of the body, and especially in phlebitis of the portal vein or mischief in the pelvis or hæmorrhoidal region." Here Sir Joseph Fayrer has no hesitation in accepting these causes in giving rise to single large as well as multiple forms of hepatic abscess. The following are grounds he furnishes for regarding his first and third forms even when associated with dysentery as not secondary to that disease: 1. "Liver abscess may, however, be unassociated with dysentery or diarrhœa."[2] It is at least noteworthy that out of the 49 cases of liver abscess at the end of the article from which these quotations are taken, cases given to illustrate "the chief points of etiological, pathological, medical, and surgical interest of tropical liver abscess," not one case can be pointed to as certainly unassociated with a bowel lesion. Of these cases, 24 had a previous history of diarrhœa or dysentery, 5 had diarrhœa and 1 blood and pus in the stools under observation; 5 are stated to have had neither diarrhœa nor dysentery, and recovered; and in 14 there is no statement of any kind regarding the bowel function at any time, and of these 3 died, 2 being examined after death, one having ulcers and the other hæmorrhoids and cancer of the rectum—that is, of the 19 that had no bowel affection, stated or implied, the only two that were examined after death had lesions of the large gut.[3] 2. "Sir Ranald Martin and others thought that liver abscess was intimately connected with diseases of the cæcum, but this has not been altogether confirmed, for of 72 cases where the cæcum was affected in only 22 was there liver abscess."[4] Had Sir Ranald Martin and others stated that most cases of cæcal ulceration are followed by liver abscess such an objection might be admitted, but these writers held that liver abscess is usually preceded by cæcal ulceration, a very different proposition. The same fallacy occurs when Sir Joseph Fayrer objects "that in temperate climates liver abscess is not always found connected with dysentery," and then quotes a number of cases of dysentery in which liver abscess did not occur.[5] 3. Sir Joseph Fayrer appeals to statistics, saying: "Of 44 specimens of liver abscess in the Pathological Museum at Netley 11 were complicated by intestinal lesions."[6] He cannot possibly have realised that these figures are of absolutely no value—nay, even misleading—unless the remaining 33 specimens were ascertained to have no intestinal lesion, though this is what is implied if the figures are to have any meaning. This implication is far from being borne out by a perusal of the Netley Museum official catalogue (1892).[7] Out of 54 (not 44) specimens from as many cases of liver abscess, in 10 (not 11) there were intestinal ulcers and sloughs or cicatrices noted; in one case the entire reference to the intestinal condition runs: "The intestines, stomach, and kidneys were healthy"; and in another: "The mucous membrane of stomach and intestines more easily torn than natural, and in many places more vascular,"[8] these being the only two cases which can be made to represent the absence of intestinal lesion, *for in 42 there is no statement of any kind as to the condition of the intestine, large or small.* Sir Joseph Fayrer has here fallen into a grievous error by disregarding the considerations pointed out at the beginning of this paper. Professor Cayley in the same volume,[9] in an article on "Tropical Disease of the Liver," says: "Acute hepatitis may run on to suppuration, and this is the *most frequent* cause of *tropical liver abscess*" (the italics are in the original). Abscess is undoubtedly an unknown result of liver congestion and inflammation at home, and I venture to regard it as at least uncommon where tropical liver abscesses occur, for the following reasons. 1. I have never seen an abscess that could be attributed to this source independently of dysentery. 2. I have not seen a case of primary hepatitis pass on to suppuration. Among such cases there are, I believe, those which we puncture without finding pus and which appear benefited by the puncture. 3. Singapore cannot be regarded as free from hepatitis by any means, but it is singularly free from liver abscess and dysentery. The West Indies are not singularly free from hepatitis; why, then, is hepatic abscess so infrequent there, as Sir Joseph Fayrer says it is, if hepatitis be the most frequent cause of these abscesses? 4. Professor Cayley, in illustration of his paper, cites eight cases of hepatitis, four of which developed into abscesses. These were single abscesses, and all four had a history of dysentery. Three had no history of dysentery and did not suppurate, but one is entitled "Congestion of the Liver leading to Acute Hepatitis, the Effect of Hot Climates and Malarial Fever, and coming on after Dysentery," and of this case the writer remarks: "In this case the symptoms, though obscure, rather point to the presence of an abscess, which very likely might have been discovered by further exploratory puncture. If there is an abscess present it may absorb or may become encysted, and may eventually show itself by more direct symptoms."[10] It is not a little curious that all Professor Cayley's cases of suppurative hepatitis should have had dysentery! In addition to the records of 53 cases referred to above in "Hygiene and Diseases of Warm Climates," I have collected 125 others from the pages of THE LANCET and *British Medical Journal* for the years 1874 to 1894, 7 cases from Councilman and Lafleur,[11] which with the 54 cases in the Netley Museum in all amount to 239. Of these, 133 died and 106 of them were examined after death, and of the latter in 59 cases there is no statement of any kind as to the condition of the bowel, 41 gave evidence of dysentery, and in 6 the following quotations contain the entire references to the intestinal condition which could by any possibility be construed as a demonstration of the absence of ulcers or cicatrices: "abdominal organs are

healthy,"[12] "the intestine was perfectly healthy,"[13] "the other organs were normal."[14] "the intestines, stomach, and kidneys were healthy,"[15] "the mucous membrane of stomach and intestines more easily torn than natural and in many places more vascular,"[16] "kidneys and intestines pale."[17] Such figures and statements surely cannot be regarded as sufficient to decide the question that tropical abscess is usually a primary liver disease. In not a single instance is it explicitly stated that no ulcer or cicatrix was found in the large intestine, which I have never seen without either of these in a fatal case of liver abscess. Surely it is not too much to look for something more explicit than the statements above quoted, supported as my own experience is by these forty-one out of forty-seven cases, reckoning fatal ones only.

Sir Joseph Fayrer appears to distinguish between the large single, tropical abscess (his first form) and the dysenteric or pyæmic (second or fourth), by the latter containing necrosed parenchyma. I have observed this condition in the large single abscess, noted also by Kartulis, Councilman, and Lafleur, Calmette, Manson, and others. I have now under observation the earliest opened case I have dealt with. In it the discharge consisted almost entirely of necrosed masses of liver tissue. My experience is that, opened later, the contents would have been pinker, with less of these masses and probably in larger quantity; later still, more fluid, yellowish and of equal consistence. The waiting game is now played less often than formerly in dealing with these as with abscesses elsewhere. The case referred to is now well. Manson recently says "it may be safely asserted that in 75 per cent. of cases of hepatic abscess a history of some degree of dysentery can be elicited. It must be recognised, however, that in this association the order of events is not always the same; usually the dysentery is antecedent to the hepatitis (abscess?); sometimes the diseases are coincident; more rarely the hepatitis (abscess?) precedes the dysentery, and in not a few cases the conditions alternate." Here Manson commences with the association of hepatic abscess and dysentery, but as he proceeds with the argument he substitutes hepatitis, and winds up thus: "It was shown that the hepatitis (abscess?) may precede the dysentery, and could not, therefore, be caused by it."[18] It was not dysentery, but its history or symptoms that were shown to be co-existent with, subsequent to, or alternating with, abscess in a minority of cases. It is not justifiable to infer that in such cases there was no dysentery antecedent to abscess formation, since even where there is no history or symptoms of dysentery at any time in a given case ulcers of the large gut may be present notwithstanding. Neither is it altogether safe to use "hepatitis" and "tropical liver abscess" as interchangeable terms in discussing this question. The occurrence of hepatitis apart from dysentery is not doubted by anyone. So far as can be ascertained, then, when liver abscess and dysentery are associated, in the majority of cases the dysentery is antecedent, and in no instance of the minority is it possible to say with certainty that dysentery was not antecedent. Before pyogenic organisms were even dreamt of in connexion with abscess, Budd maintained, as every authority now does, the secondary nature of those abscesses included in Sir Joseph Fayrer's fourth division, but opposed by many; he also held that tropical liver abscess was secondary to ulceration of the large gut. From time to time pathologists have shown that in certain cases of dysentery, if not in all, submucous suppuration occurs in varying degrees, taking part in the formation of sloughs of varying sizes. Here, then, we have pyogenic organisms in the dysenteric lesion, in a region as closely related to the liver as suppurative mischief in the pelvic or hæmorrhoidal region, and just as by no means in every case of this latter kind, so not in every case of dysentery, can secondary liver abscess be expected to occur. Speaking of this matter, Manson lately says, "At one time if was held that the abscess was caused by the absorption of pus by the portal vein from the dysenteric ulcers and from suppurative phlebitis, which was supposed to be present in the intestinal radicles of that vessel. But no such phlebitis was demonstrated."[19] Surely a process involving submucous suppuration, necrosis, ulceration, or sloughing of the mucous coat of the large gut, supplies the required affection of the intestinal radicles of the portal vein, for it is impossible to imagine these radicles escaping. Why is it that typhoid ulceration is so seldom, if ever, associated with liver abscess even in the East Indies? This form of ulceration is confined to glands at the free margin mostly of the lower end of the small bowel, whereas in dysentery the ulcers are not confined to gland tissue or any particular part of the large bowel circumference. But what is probably of greatest importance is the part played by the suppurative process which occurs so frequently in dysentery, but so rarely, and if at all to such a small extent, in typhoid ulceration. Yet one other aspect of the matter has to be dealt with. The finding of an amœba in some of these abscesses is considered by most of the finders as affording further proof of their secondary relation to dysentery, more especially to what is termed "amœbic dysentery." There can be little doubt that the terms "dysentery" and "dysenteric ulceration" cover more than one disease process. Manson has recorded[20] the first case in England in which an amœba has been found in liver abscess, terming it an "amœbic liver abscess," and suggests that it was caused, in the absence of dysentery and the known pyogenic organism, by the dysentery amœba. The patient died, but unfortunately no post-mortem examination was made to decide that this was not one of those cases where the patient had dysentery without being aware of it. The view that abscess of liver, when not a part of a general pyæmia, is rarely primary, but usually secondary to lesions occurring in close relation to some part of the portal circulation; to those lesions in which pyogenic organisms (micrococci, and it may be amœbæ) are concerned, this view claims no more for suppuration in the liver than is being demonstrated more and more every day for suppurative processes in the brain, which latter are rarely primary.

CASES ILLUSTRATING THE SURGERY OF THE KIDNEY.

BY J. KNOWSLEY THORNTON, M.B., C.M. EDIN.,
CONSULTING SURGEON TO THE SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN, AND TO THE NEW HOSPITAL FOR WOMEN, AND THE GROSVENOR HOSPITAL FOR WOMEN.

(*Continued from p. 1429 of Vol. I., 1895.*)

BEFORE proceeding to the continuation of my cases I must record the safe delivery and good health of mother and son in Case 23, operated upon in 1888, and incidentally referred to in my last communication. This is the second of the tuberculous cases which has not only made a perfect recovery, but has also passed through pregnancy without any unusual complication. I have also the satisfaction of recording the complete recovery of the patient upon whom I performed Abernethy's operation for tying the iliac artery in order to get at two small stones in the lower end of the ureter. I heard from her a few days ago that she had been able to accompany the guns, walking over the moors in Scotland on several occasions this autumn, and for the first time. I have also received a very satisfactory report from my seventh case of nephrorrhaphy. The patient had before the operation been a confirmed invalid for years, and now reports herself as quite well and able to walk and swim, jumping off a boat into the sea. I will now proceed with the record of my cases of nephrotomy, following the same plan adopted with the nephrectomies, and giving a very brief note of the less interesting cases and a more detailed account of the unusual cases. I have already published my first thirteen nephro-lithotomies, in which there were one fatal case and twelve recoveries.[1] The present series commences with Case 14.

CASE 14.—The patient was a woman aged sixty-two years, small, thin, and fragile. The urine was of low specific gravity, containing much mucus, a little albumin, many blood cells, and clumps of granulation cells visible to the naked eye as minute white specks in the urine. There was no pain or difficulty in urinating. On palpation both kidneys could be distinctly felt, and were of normal size, the right being

[1] Harveian Lectures: Surgery of the Kidneys. By J. Knowsley Thornton. Chas. Griffin and Co. 1889.

Digitized by Google

very markedly tender. Three years before her admission into the Samaritan Free Hospital she was suddenly seized with violent pain in the abdomen while sitting in church; it lasted till night and recurred next day, and had continued more or less ever since, rarely being absent for more than a day or two at a time. It was sharp and stabbing, and shot over the abdomen and across the back. It was chiefly on the right side, but occasionally crossed to the left. I came to the conclusion that there was a calculus in her right kidney and removed it on March 30th, 1890, by the combined abdominal and loin incisions. It was an hourglass-shaped oxalate calculus in the pelvis of the right kidney. The left kidney was normal. Recovery was smooth and complete. The stone was about an inch long and had a very rough surface, and had evidently been adherent to the lining of the pelvis and ureter over nearly its whole surface.

CASE 15.—A married woman aged thirty-one years was placed under my care at the Samaritan Free Hospital by my friend Dr. Hamilton Bland. She had borne six children. On examining her pelvis I found a retroflexed, somewhat fixed, and tender uterus, and a very tender swelling about the size of a horse-bean at the entrance of the left ureter into the bladder. The urine had been thick for about twelve months; there had never been pain or difficulty in passing it, a symptom the absence of which I omitted to note in Case 14. The urine was of normal specific gravity, and contained a trace of albumin and a considerable deposit of pus and phosphates. She had passed a quantity of small stones about two months before admission, and some every time she passed water for about a fortnight. She first noticed pain in the left kidney when carrying her last child four years and a half ago. After its birth, while taking a long walk with the child in her arms, she was suddenly seized with severe pain in the abdomen, and a swelling came in the left side. She was laid up for six weeks, and the lump and pain recurred whenever she got about. I operated by the combined incision on April 23rd, 1890. I found the right kidney large, smooth, and healthy. In the pelvis of the left kidney there was a large stone. I removed it quickly and without difficulty through a small lumbar incision, and found that it was branched and showed two broken surfaces and several facets. Another piece was then extracted, fitting the largest broken surface. Then another large stone was detected and removed with difficulty; it had a deep groove in it where it had been grasped in the mouth of a calyx. Numerous small flat stones and some other broken fragments were also removed. The kidney was washed out with a solution of corrosive sublimate and the lumbar wound drained. I then found that the tender pelvic swelling was a hydro-salpinx and removed it. The patient made a slow recovery, only leaving the hospital on June 13th.

CASE 16.—A married woman aged thirty-one years had passed offensive urine from girlhood, the bladder not emptying itself properly. When seventeen years of age her horse ran away with her and she was strained internally and passed blood in the urine. Four years later there was an attack of pain and swelling in the left loin, and she had ever since had recurrences at frequent intervals. The attacks used to be frequent and short and without fever, but latterly had been prolonged and accompanied by severe fever, but at longer intervals. There was frequent and painful micturition during an attack, very little urine being passed. Her six children are all strong and healthy. The urine was of good specific gravity, with a small quantity of albumin, a few pus cells, oxalates, uric acid crystals, and renal and ureteral epithelium. I operated on April 24th, 1890, and found the exit of the left ureter from the pelvis blocked by a small stone and the kidney reduced to a mere bag, and I decided to remove it, but on examining the right kidney I found it also cystic and unhealthy and so contented myself with free incision and drainage of the left kidney. She made a slow recovery and remains in fairly good health, but she is subject to attacks of pain and fulness in the left loin, accompanied by fever, when she gets a chill or is over-fatigued.

CASE 17.—A married man aged thirty-one years had suffered from pain in the left renal region from childhood, and from time to time there had been blood in the urine. He now suffered from almost constant pain with occasional severe exacerbations laying him up for days at a time. On May 20th, 1890, I removed one large dark-brown oxalate calculus very irregular in shape and several smaller ones from the left kidney. The other kidney was quite healthy. The operation was rapid and without a hitch of any kind, there being very little handling of the kidney, a small, clean incision, and the stones were quickly and easily extracted. I emphasise these facts because of the subsequent history. He made an absolutely perfect recovery for a fortnight, when he was visited for the first time by his wife; he admitted much sexual excitement, followed by a nocturnal emission and pain in the left renal region; this recurred occasionally, and there was also pain on micturition from time to time. He went home apparently quite well at the end of three weeks and remained quite well for some months, still occasionally complaining of pain in the left loin. Then an abscess formed in the neighbourhood of the kidney and burst into the pleura, and he had pleuro-pneumonia and pneumo-thorax and died about seven months after the operation. I only heard of it some time afterwards. This unfortunate ending to a successful operation is useful as a warning to exercise great care in the after-treatment of these cases. I allowed the patient to get up too soon and to go home too soon, especially in view of the result of his wife's visit to him in town. I have no doubt that there was some disturbance round the kidney then, and that it never got quite right and was aggravated by sexual intercourse on his return home. I warned him to be careful, but saw that he did not believe in the necessity. I have not any good record of this case after he left my care, but it is interesting to compare it with Case 28 among the nephrectomies published in the Clinical Society's Transactions, vol. xxiii., p. 150, by Dr. Myrtle of Harrogate and myself, in which a large perinephric abscess burst through the lung, with complete recovery. The points I wish to emphasise are the importance of prolonged rest and care after these operations to allow of thorough consolidation of the cellular tissue about the renal wound, and the insidious way in which an abscess will form in these cases when the patient is apparently well. In neither of these cases was the presence of the abscess suspected till it burst into the chest. Similar suppuration occurred round the kidney in another case to be recorded in this series after a very smooth recovery.

CASE 18.—The patient was a married woman aged thirty-two years. I have lost the notes of this case taken before operation, but she had been very decidedly losing health, and her condition had been much worse after an attack of influenza. The diagnosis of right renal calculus appeared to me to be clear. I had no difficulty in finding and cutting down upon the stone, but it was so soft that it broke up in the forceps, and I had to wash it away by repeated injections. The process was a long one and there was a great deal of shock; whether there was also too great absorption of carbolic acid has occurred to me as aiding in the unfortunate result. The patient was in a low and depressed condition before the operation, and on the morning of the day the temperature was very much below normal. I left the patient without any uneasiness, but on looking in just before dinner I was surprised to find that she was still unconscious, and, indeed, had never rallied at all from the operation. She was breathing stertorously and was almost pulseless, the skin being cold and the respiration feeble and irregular. Later in the evening she recovered consciousness for a few hours, but could not speak correctly. She died twenty-seven hours after the operation, with complete suppression of urine four hours before death. I have never in any other case met with a stone of this kind; it appeared to be made up entirely of soft phosphatic matter, which at once crumbled away when I grasped it with the forceps, and I could not find any hard nucleus. When I first felt it, it was an almond-shaped stone of about the size of a haricot bean occupying the pelvis at the mouth of the ureter.

CASE 19.—A single woman aged twenty-eight years, who had suffered from symptoms of left renal calculus for many years, and for two years had been a confirmed invalid, was brought to me in the spring of 1891 by Mr. Aikin. The kidney was quite out of reach under the ribs, and I could not get a suspicion of tenderness by palpation, but all the other symptoms were so marked that I had no hesitation in recommending operation. The urine was of good specific gravity, contained no albumin, much mucus, some pus, and blood cells, and deposited lithates freely. I operated on March 9th, 1891, and was some time in finding the stone, which projected from one of the calyces into the pelvis, in which position it was so firmly grasped that I had great difficulty in extracting it. The stone was a pear-shaped oxalate one

Digitized by Google

covered with sharp spicules and had a large angular projection which had prevented its escape from the calyx and caused the difficulty in its extraction. The patient made a good recovery in spite of the terrible shock of losing the sister who lived with her, who died after a few days' illness from diphtheria while she was in the same house and not yet well enough to leave her room after the operation. She is now married and in excellent health, and able thoroughly to enjoy life.

CASE 20.—A young man aged twenty-five years, single, had suffered from symptoms of calculus for two years before I saw him. There was marked pain on pressure over the situation of the junction of the ureter and pelvis of the left kidney. Pain was almost constant, but it was worse after any unusual exertion, and he had had several severe attacks. I found several small stones in the pelvis of the kidney; the largest broke in extraction, and I was eventually obliged to wash them out of the kidney with a continuous stream of hot water, which was useful in checking the hæmorrhage, the latter being unusually severe, and kept up, I have no doubt, by his taking the chloroform very badly and getting all his tissues loaded with venous blood. He made a good recovery, but has always had more or less blood in his urine since the operation, and latterly has had other symptoms which make me fear that a stone must have been left behind, so that I am going to reopen the kidney. I should have mentioned that the urine examined before operation was of low specific gravity, and contained a trace of albumin, oxalates, and blood cells. The urine passed just before I first examined him was clear, and that passed just after the examination contained blood.

CASE 21.—The patient was a young married woman, seen in consultation with Dr. Stivens and Sir William Broadbent. The exact nature of the illness was very obscure, but renal calculus was not suspected. I made a small incision in the loin and then pushed Sir Joseph Fayrer's grooved trocar cautiously into the kidney and let out a lot of pus. I enlarged the opening with a bistoury slid along the groove in the trocar, and on introducing my finger found a rough angular stone in the pelvis; this I removed, and then well flushed the kidney with warm water and drained it. Convalescence was very slow and there were many relapses, the tube having to be reintroduced over and over again in consequence of fresh suppuration in the kidney after she had apparently recovered. In some of these illnesses I saw her, and in some she was under the care of others, but she eventually got well.

CASE 22.—The patient was a single woman aged thirty-five years, seen in consultation with Dr. Ord and Dr. Falls. A right renal calculus was diagnosed and removed without difficulty; recovery in all respects was satisfactory, as is also her present condition.

CASE 23.—This was that of a young married woman upon whom I had operated for ovarian tumour many years before, removing a solid brain-like sarcoma, which I thought was almost certain to recur speedily; but she got quite well and bore several children after the operation. In September, 1891, seven months after her last pregnancy, she began to suffer much pain in the left renal region; during the pregnancy she had suffered much from what was thought to be severe cystitis, and when she got about again had some attacks of renal colic. She was attended by Mr. Maurice of Reading, and I had frequent communication with him about the case from time to time after the ovariotomy and up to the time of this final illness. I operated by the combined method in November, 1892, and quickly found a stone in the left kidney—this was one of the quickest operations I ever undertook. I could detect nothing wrong with the other kidney except that it was rather large and loose. She appeared at first to be making a rapid recovery, but then had a serious relapse, and I had to reopen the lumbar wound into the kidney. This gave relief for a time, but her condition was not satisfactory, and she began to complain of pain in the other kidney, which I found to be distinctly enlarging, and eventually it became so painful that I incised it through the loin at her urgent request, letting out pus and blood. Both kidneys continued to discharge, still giving her much pain, and she rapidly emaciated and died. I did not obtain a post-mortem examination, but I have little doubt, from the symptoms observed during the progress of the illness, that there was a sudden outburst of malignant disease in both kidneys. Dr. Guillemard of Southsea, who had attended her shortly before the operation, told me that he had on two occasions after she had had attacks of hæmorrhage found masses in the urine which appeared to him to be casts of the pelvis and upper end of the ureter, more or less coated with phosphates, and similar masses escaped from both kidneys after the loin openings were made free. I have seen similar casts of the ureter in other cases associated with malignant disease invading the pelvis of the kidney, but I have never met with them in any case of renal calculus. Supposing that the disease was already in progress in the left kidney when I removed the stone, it might well in an early stage have escaped my notice; then came the marked improvement and apparent recovery, which lasted as long as the kidney was freely drained and ended when I allowed the wound in the kidney to close up. The other kidney meantime becoming infected as a direct result of the wounds in the left kidney—watching the case closely and anxiously as I did, for she was a great personal friend as well as patient—this was the only explanation I could find for the symptoms and mode of death.

(To be continued.)

CASE OF RECOVERY AFTER TREPHINING IN TUBERCULOUS MENINGITIS.[1]

BY JAMES KERR, M.A., M.D. CANTAB.,
MEDICAL SUPERINTENDENT, BRADFORD SCHOOL BOARD.

THIS subject having been recently brought forward, the notes of the following case occurring in private practice may be of interest, particularly as at the time it was believed by those concerned to be the first time that the operation had been deliberately performed in this disease.

The patient, aged ten years, was a little light-haired boy of slight build, with marked internal strabismus and wearing glasses (+ 4 dioptres); he is clever in many ways, being, for instance, the best fiddler in the school band, but backward in ordinary school work. His father is clever in a low mental way and generally out of work. He has a neurotic mother, and a sister with hystero-epilepsy. There is on both sides a strong tuberculous family history; the patient's maternal uncle is reported to have died from tuberculous meningitis. The boy's illness began indefinitely; some abdominal pains had been complained of for about two months, and for two or three weeks he had been out of sorts and had done many strange things. He had lately had headaches, and on March 13th, 1895, and again on the 15th, was sent home from school ill. On the 16th he went in from play with a very bad headache, and was so ill that Mr. G. H. Dodd was consulted, who sent the patient to me on the following day. I found him complaining of headache, with intense exacerbations and intolerance of light and sound. He was feverish, with a dirty tongue and suffering from constipation. There was no other indication of ill-health; the lungs were healthy, and there was no optic neuritis or *tache cérébrale*. During the next ten days he steadily got worse, the pulse varying from 88 to 100, and the temperature from 99° to 100°F., being generally highest in the morning. He had intense exacerbating headache, night sweats, loss of flesh, cerebral vomiting, and delirium, also wetting the bed, and a meningitic cry and attitude were developing. On March 24th he was very excitable; he said he saw red lights and complained of his neck being stiff on the right side behind. He felt as if falling to the right when standing, but actually tended to fall backwards. He generally lay on the right side and sometimes knelt with the head on the pillows. On March 26th it was noticed that he slept much with his eyes open, the hands flexed, and the knees drawn up. There was optic neuritis in the left eye, the edges of the disc being pulpy and indistinct, with some lymph about the vessels; the right disc was normal. The bowels had not been opened for five days. During the evening there was a general convulsion, the head being drawn back and to the right. He was semi-conscious and in great pain, and was put freely on opium in order to lessen the distress. An operation having been consented to, I at 11 A.M. next day gave chloroform, and Dr. T. Jason Wood, assisted by Mr. Dodd, trephined one and a quarter inches above and the same distance behind the left meatus auditorius externus, removing a half-inch button. The dura mater bulged considerably; it was reflected, very little fluid escaping and the brain not pulsating. A fine cannula

[1] The patient was shown at the meeting of the Bradford Medico-Chirurgical Society on May 7th, 1895.

Digitized by Google

was passed twice two and a half inches in the direction of the ventricle; no fluid escaped, but the brain began to pulsate. Half a dozen strands of silkworm gut were then with difficulty passed beneath the membranes towards the base; they seemed to go about one and three-quarter inches downwards, the free end being brought out at the edge of the wound, which was then stitched, dusted with iodoform, and covered with dry sublimate wool. After six hours' deep sleep, due probably to two and a half grains of opium given during the eighteen hours before the operation, the child was much better. Nine hours after the operation he was clear mentally, and free from headache for the first time for at least ten days: next day the bowels were moved after calomel. Sixty hours after the operation the dressing was changed, clear fluid draining off in small quantity; subsequently the dressings were changed every third day. On the fifth day after the operation the neuritis was noted as still being well marked. On the sixth day the patient suffered from headache for three hours; he had delusions, saw little men in the room, and later had a general convulsion. On removing the dressing the wound and drainage-tube were found to be sealed with a hard scab; this was loosened, and there was no further trouble. The drainage-tube was finally removed on the seventeenth day, the discharge having much diminished, and within a month of the operation the boy was playing cricket. The temperature then remained at from 99° to 100°, at intervals he had night sweats, and during the early part of September a recurrence of the paroxysmal headache with vomiting occurred, causing anxiety for nearly a fortnight. There was no advance in the symptoms, the vomiting was chiefly after food, and it was thought that a great part of the illness was hysterical, but it subsided gradually, and the patient now seems to be well, except for his regularly elevated temperature.

Remarks.—The whole course of the illness up to the time of the operation was typical of tuberculous meningitis. The slight localising indications pointed to most irritation about the base on the left side. The neuritis was indefinite for localisation—it was taken, if anything, as in favour of the other symptoms. The operation was performed with the idea that the affection was most severe about the base on the left side; it was followed at once by disappearance of the headache. The remission of temperature after operation noted in cases which have since been published was absent in this case. It is possible, having regard to the continued feverishness and the illness in September, that there is some massive tubercle about the base, and that there was an intercurrent attack of meningitis, but there can scarcely be a doubt that the operation relieved the symptoms and averted impending death. One would judge from this case that trephining is justifiable in tuberculous meningitis, if only to relieve headache, and ought to be done as soon as the diagnosis is clear, before the paralytic stage is reached, and that drainage can be kept up with advantage for a considerable time.

Bradford, Yorks.

IRISH MEDICAL SCHOOLS' AND GRADUATES' ASSOCIATION.—The autumn general meeting will take place at the Café Monico on Tuesday, Nov. 12th, at 6.30 P.M., and the autumn dinner of the Association at the same place at 7 P.M. Lord Russell of Killowen, the Lord Chief Justice of England, will be the guest of the Association on the occasion.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.—The annual meeting of this society was held in the medical library of University College on Oct. 9th. Mr. A. W. Prichard, President, gave his inaugural address, which dealt chiefly with the surgical aspect of disease and accident as occurring in the boys of Clifton College. He mentioned numerous interesting cases, and insisted that there was a great benefit obtained by the following out of the course of athletics and games as arranged at that great public school. The honorary secretary (Mr. Paul Bush) read his annual report, as did also the assistant editor and honorary librarian (Mr. L. M. Griffiths). These reports were adopted. The following officers were elected:—President Elect: Dr. Aust Lawrence. Honorary Secretary: Mr. J. Paul Bush. Committee: Dr. Michell Clarke, Mr. Dacre, Mr. W. Harsant, Dr. B. Rogers, Dr. Shaw, and Mr. Munro Smith. Mr. L. M. Griffiths, Dr. Parker, and Dr. Jas. Swain were elected to serve on the Library Committee.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum propria collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.* lib. iv. Proœmium.

ST. THOMAS'S HOSPITAL.

A CASE OF INJURY TO THE ASCENDING COLON; FORMATION OF INTRA-PERITONEAL ABSCESS; INCISION; FÆCAL FISTULA; RECOVERY.

(Under the care of Mr. G. H. MAKINS.)

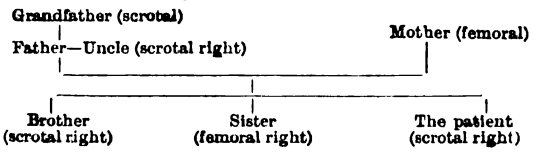
THIS is one of those cases which serve to emphasise the teaching that every injury to the abdomen should be kept under careful observation for several days, for it is a well-understood fact that serious injury may be done to the abdominal contents by direct violence without any definite evidence of its extent at the time or within a few hours. Shock is a very variable symptom and unreliable, therefore the absence of shock should not be looked upon as a proof that no lesion has followed such a severe nipping of the abdomen as had been experienced here. It is possibly due to the great care exercised by the patient's medical attendant that more serious consequences did not follow before the 28th. In the larger number of instances of intestinal injury the small intestines, being the most exposed, are damaged, and the colon escapes. Such cases as the following are very rare, almost unknown, therefore the remarks by Mr. Makins will be found very valuable.

The patient was a man aged twenty-four years, whose family and previous personal histories were good. On Aug. 1st, 1895, while engaged at work, he was caught between two trucks passing each other. He was forcibly turned round and round between the two waggons until they came to a standstill, when he dropped to the ground. He was taken to the hospital and examined, but as only superficial contusions were detected he was taken home: here, however, he was kept in bed by his medical attendant, Dr. Crossman. The patient suffered from some pain in the abdomen, which was not of a severe character, but not from sickness or any other symptom pointing directly to the intestinal tract. His temperature, however, was raised above normal, reaching 100° F. or more in the evenings, and his appearance suggested internal mischief. On the 26th he was allowed to get up, and he was then seized with sudden pain in the right half of the abdomen, and his urine was found to contain a considerable quantity of blood. His bowels continued to act, though somewhat irregularly, and there was no sickness, but a distinct swelling was to be felt in the right half of the abdomen. On Sept. 3rd he was sent to St. Thomas's Hospital by Dr. Crossman. There was some emaciation, which had been gradually increasing; the face was thin and flushed, and he complained of much pain in the abdomen, lying in the supine position with the knees drawn up. On examination of the abdomen a large, tense, elastic swelling with ill-defined margins was found in the right half, extending almost from the lower costal margins to Poupart's ligament. It was dull on percussion, the dulness, however, not extending into the right flank, and in the lower part fluctuation was distinct. The evening temperature reached 100°. The urine contained a trace of albumin, but no blood. On the 6th he was anæsthetised with ether, and an incision was made over the most prominent part of the swelling, at the outer margin of the rectus. The abdominal wall was infiltrated and stiffened, but no pus was met with until the peritoneal cavity was reached. An irregular cavity walled in by intestine was then opened, the ascending colon being firmly adherent to the anterior abdominal wall at the outer limit of the space. The pus was extremely offensive, fæcal in odour, and dirty-coloured, but no distinct fæcal lumps were present. The cavity was abundantly lined with lymph, and no definite opening in the intestine could be discovered by the escape of either fæces or gas. A large drainage-tube was inserted, and the wound was partly sutured with silkworm gut after the

Digitized by Google

cavity had been thoroughly flushed with hot sterilised water. On the 7th he was found to have been very comfortable and to have slept well, there being no pain. The wound was dressed, the discharge from the tube being distinctly fæcal. For the next three days a small amount of fæces escaped daily, and the purulent discharge was abundant. After the 11th, however, there was no further appearance of fæces, and the pus, though still foul, became gradually sweeter and less abundant. He steadily improved in his general condition, the temperature remaining normal, and he rapidly regained flesh. The tube was gradually shortened and finally removed on the 30th, little induration remaining around the wound. On Oct. 7th the latter had entirely closed, and on the 9th he left the hospital well.

Remarks by Mr. MAKINS.—The main interest in the above case seems to centre in the question as to whether the original injury to the colon was intra- or extra-peritoneal in position. When such accidents are not rapidly fatal the explanation is usually to be found in the fact that the rent in the colon has occurred in the extra-peritoneal segment, hence extravasation takes place into the retro-peritoneal tissue of the loin, and the general peritoneal cavity escapes. In these cases, however, the abscess usually forms in the loin, while in the above instance the abscess was intra-peritoneal and also within the line of the ascending colon. Two modes of explanation seem to suggest themselves. First of all there seems to be little doubt that the original injury did not amount to an actual rent, or, if it did, that the rent was very small in extent. Under these circumstances adhesive inflammation may at once have commenced, and when the serious trouble took place on Aug. 26th there may have been some preparation for the limitation of the fæcal abscess. It seems, however, more likely that the injury in this case was in the posterior segment, the injury in the first instance being perhaps either a very slight rupture or severe contusion without an immediate rent, escape of the contents of the gut occurring only on the twenty-fifth day, when the patient tried to get about (Aug. 26th). The simultaneous occurrence of hæmaturia seems to afford corroborative evidence of some value in localising the injury to the inner side of the bowel—i.e., that nearest to the right kidney; while the adhesion of the bowel to the anterior abdominal wall noted at the time of operation also seems to point to the bowel having been pressed forward. Hence the absence of a palpable swelling of the loin in the usual position would be explained by the fact that the original injury, affecting the colon and kidney, so damaged the peritoneum covering them both as to render the passage of escaping fæces and pus more easy in the direction of the abdominal cavity than into the loin, and this is perhaps the more likely when the chronicity of the sequence of events is taken into account, the retro-peritoneal tissue in the immediate neighbourhood of the injury having become more dense from inflammatory induration. The dark colour and lumpy nature of the fæcal discharge seemed to leave no doubt that the colon was the portion of bowel injured.



SWANSEA HOSPITAL.

A FAMILY HISTORY OF HERNIÆ.

(Under the care of Mr. J. KYNASTON COUCH.)

A SERIES of cases of hernia all occurring in one family has not often been brought forward. The tendency to defective construction at those spots in the abdominal wall where the anatomical design is weakest is hereditary—as would be expected; but the fact is so very familiar to all that surgeons have been prevented from publishing their experiences. In this interesting series it will be seen that this particular patient had a double vicious history, both parents having been affected, the father with the right scrotal hernia common to *his* father, brother, and son, and the mother also having a femoral hernia. It would seem most probable that the lad inherited his defect—over-patent inguinal rings—from his father, but the laxness of tissue present in his mother's case, and shared by his sister, as shown by their possession of femoral herniæ, may have counted for something in the size of the protruded mass. For the notes of the case we are indebted to Dr. Stephen Floyd, resident medical officer.

A well-developed boy aged seven months was admitted into Swansea Hospital with an enormous congenital scrotal hernia. It was as large as a good-sized orange and quite obliterated the penis. On radical cure being performed it was found to contain a great part of the small intestine, the cæcum, and part of the ascending colon. The patient made a perfect recovery. The appended schedule shows the different members of the family affected.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

On Posture in its Relation to Surgical Operations under Anæsthetics.

THE first meeting of this society for the present session took place on Oct. 22nd, Mr. HUTCHINSON, President, being in the chair.

Dr. ORD presented to the society the volume on "Climatology and Balneology" recently published by Messrs. Macmillan and Co. A committee was appointed by the society during the presidency of Sir Edward Sieveking, and the present book was the first volume of the work. It comprehended chiefly the climatology of the south coast of England and a description of the more important medicinal springs of Great Britain. Dr. Dickinson had dealt with Cornwall and the Scilly Isles, Dr. Symes Thompson and Dr. Lazarus-Barlow had described Devonshire and the Channel Islands, Dr. Mitchell Bruce had undertaken the compilation of that section dealing with Somerset, Dorset, and Hants, while the south-eastern counties—Surrey, Sussex, and Kent—had fallen to the lot of Dr. Ewart. All had worked zealously, and it was hoped that the medical public would appreciate the results of their labours.—The PRESIDENT remarked that the committee was an innovation on what had been accomplished by the society in the past, and he alluded in grateful terms to the valuable services rendered by Dr. Ord, the chairman of the committee.—Sir EDWARD SIEVEKING considered that the committee, which had admirably managed its business, should be made a standing one, to which the profession could turn in case of requiring advice or desiring to record climatological or other phenomena. He moved a vote of thanks to the committee and eulogised especially the services of the secretary, Dr. Archibald Garrod.—Dr. DICKINSON said that the committee was indebted to many observers in various parts of the country for valuable information. He proposed that each of these gentlemen should be presented with a copy of that paper in which his contribution appeared.—The vote of thanks to the committee was carried unanimously. The President presented the annual volume of the Transactions for 1895.

Dr. FREDERIC HEWITT and Mr. MARMADUKE SHEILD brought forward a paper on Posture in its Relation to Surgical Operations under Anæsthetics. They pointed out that the posture of a patient prior to, during, and after a surgical operation under an anæsthetic was a matter of considerable importance to the surgeon, to the anæsthetist, and in many cases to the patient himself. The subject was discussed under the following headings:—1. The posture of the head in its relation to that of the trunk; extension, flexion, and rotation of the head were considered. Stress was laid upon keeping the head, whenever practicable, in the longitudinal axis of the body. The circumstances which favoured the entrance of blood into the larynx and trachea were defined. 2. The influence of the force of gravity upon the circulation and respiration. The observations of Snow, the Hyderabad Commission, and of Dr. Leonard Hill were quoted; and the administration of anæsthetics to patients in the sitting and semi-recumbent postures was discussed. 3. The postures of surgery individually considered: (*a*) The dorsal, supine, or horizontal posture; the advantages of keeping the head turned to one side, and the disadvantages

Digitized by Google

of allowing a patient to lie face upwards, and with the head slightly extended; (*b*) the dorso-lateral posture; (*c*) the lateral posture; its advantages in most major operations within or about the mouth and nose; operations for empyema. (*d*) The latero-prone and prone postures; necessity for caution when patients of certain types were placed in these positions. (*e*) The semi-recumbent posture; its disadvantages except in a few special cases. (*f*) The sitting posture. (*g*) Special postures, including the lithotomy, the semi-inverted, Trendelenburg's, and the knee-elbow. 4. The posture of the patient after the operation. Remarks were made concerning the raising of patients for bandaging &c., the application of bandages after an empyema operation, and the appropriate positions for patients when the circulation was feeble. Dr. Hewitt and Mr. Sheild strongly urged the advantages of at once turning patients upon the side after an operation, provided, of course, that there were no special contra-indications.—The PRESIDENT said that the subject dealt with in this manner was a novel one, and Dr. Hewitt and Mr. Sheild had handled it in a very thorough and painstaking way.—Mr. R. GILL regretted that the chief part of the paper was occupied with generalities, and that a particular anæsthetic was not mentioned when dealing with a particular posture. He could not agree that many of the positions described were so dangerous as had been maintained in the paper; for instance, in the supine posture with the head extended it must be very rare for blood or vomit to find its way into the air passages.—The adjournment of the debate was agreed to, being moved by Dr. SCANES SPICER and seconded by Dr. SANSOM. Dr. Sansom added that he regarded the paper as a most valuable one, and held that alterations of posture under anæsthetics were of the most extreme moment and importance.

OPHTHALMOLOGICAL SOCIETY.

President's Address.—Bilateral Glioma of the Retina cured by Enucleation of the Two Eyes.—Detachment of Choroid.—Exhibition of Specimens.

A MEETING of this society was held on Oct. 17th, Mr. NETTLESHIP, President, being in the chair.

Mr. NETTLESHIP thanked the members for the honour done him in his election to the presidental chair. He adverted to his association sixteen years previously with those energetic spirits who were foremost in establishing the society, among whom he specially mentioned Dr. Brailey, Dr. Stephen Mackenzie, and the late James Adams, who influenced Sir William Bowman to launch the society. The President paid a graceful compliment to his predecessor, and pointed out that the Ophthalmological Society was a great educational institution and would continue so while its members preserved open minds and kept abreast of the growing knowledge of their subject. He spoke in high terms of the value of special hospitals and the special departments of general hospitals, with the friendly rivalry and intercommunication which greatly advanced the knowledge and skill of their officers. The material for study in ophthalmology was inexhaustible, but he thought the subjects might be usefully divided into three classes—namely, (1) rare diseases and conditions which were worthy of record and of which he instanced numerous cases; (2) subjects capable of final settlement by collective information submitted to a committee or discussion; and (3) subjects which could best be treated in separate monographs.

Mr. TREACHER COLLINS read a paper on Four Cases of Bilateral Glioma of the Retina cured by Enucleation of the Two Eyes. He first referred to the paper in which Mr. Lawford and he had shown that there was no authentic record of a case in which a gliomatous growth had recurred later than three years after enucleation of an eye for that disease. He related histories of the following four cases. Case 1. A boy who had his right eye excised for glioma when five months old and his left eye three years later. Three and a half years after the removal of his second eye he was alive and well, and there was no sign of any recurrence. Case 2. A girl whose left eye was excised for glioma when five months old and the right eye nine months later. She was seen to be in perfect health four years and seven months after the removal of the second eye. Case 3. A girl whose left eye was excised for glioma when ten months old and the right eye thirteen months later. Four years after removal of the second eye she was in good health and there was no sign of any recurrence. Case 4. A boy both of whose eyes were excised for glioma when he was one year and four months old, the left being a shrunken one. Three years and three months later he was in good health and had no sign of any recurrence. Seeing that all these four patients were alive and in good health, without any sign of recurrence, after an interval of more than three years from the date of removal of the second eye—that is, after the longest interval at which there is any authentic record of a recurrence having occurred—he thought he might justly claim that they were cured.—Mr. LANG reported three cases, two of which were described by Mr. Collins. In the third case operation was refused and only consented to when pain occurred and after the nerve was affected, the child dying at about eight years old with secondary growth.—Mr. LAWFORD quoted a case in which the first eye was removed at two months. Two and a half years later the second eye was affected; operation was refused and two years later sight was almost gone. At four years the eye became painful and was removed, but the nerve was invaded and the ultimate fate of the patient was still undecided.—Mr. P. SMITH related a case in which it was recorded that both eyes had been removed for cancer, the patient being about eight years old. This was at the Birmingham Infirmary.—The PRESIDENT recorded a case, the patient being now living, in which both eyes had been removed, the second three years ago.

Mr. C. DEVEREUX MARSHALL read a paper on Detachment of the Choroid. Three cases had recently come under his notice. The first case was the eye of a youth aged twenty years who suffered from glaucoma. Iridectomy was done, and three days later the eye became very painful owing to a large hæmorrhage having taken place beneath the choroid. On examining it after removal the choroid and retina were found to be completely detached. The second case was that of a man aged sixty years, who had suffered from glaucoma. Iridectomy was done, but the eye shrank and was removed. There was an extensive detachment of the retina and choroid; the subchoroidal space was filled with new tissue in which cyst-like spaces were developed. Microscopic examination proved it to be the much-thickened lamina supra-choroidea and lamina fusca; the small spaces contained pigment and were probably lymph channels. The third case was that of a man aged sixty-eight years who had a cataract extracted; the vision equalled $\frac{6}{18}$ and J. 1 afterwards, but six months later it failed. As it was feared that the eye contained a new growth it was removed. There was almost complete detachment of the choroid and retina; the only places where the coats remained attached to the sclerotic were where the vessels and nerves penetrated; thus there were four large balloon-shaped detachments, the subchoroidal space containing nothing but serous exudation. The first case is similar to that condition met with after an accident resulting in the loss of a large quantity of vitreous, and it is occasionally seen after cataract extraction, but here the hæmorrhage probably did not come on for three days after the operation, and there was no loss of vitreous. The last case is the most uncommon. The detachment probably came about as the result of (*a*) hyalitis, leading to shrinking of the vitreous; (*b*) choroido-retinitis; and (*c*) serous exudation poured out between the choroid and sclerotic. The diagnosis previously to removal is most difficult. The tension is usually diminished, and this is the most distinctive feature between the simple detachment and that due to a growth.

The following were the card specimens exhibited:—

Dr. ERNEST CLARKE: (1) Rare Form of Nystagmus; and (2) Orbital Tumour.

Dr. MOTT and Mr. TREACHER COLLINS: Case of Exophthalmos with Trigeminal Hemianalgesia.

Mr. KENNETH CAMPBELL: Case of Anophthalmos.

Mr. A. S. MORTON: Snellen's Operation for Symblepharon.

Mr. HIGGENS: Unusual Form of Conjunctivitis.

Mr. LAWFORD: Case of Retinitis Circinata.

HARVEIAN SOCIETY OF LONDON.

The Climate of Egypt.

A MEETING of this society was held on Oct. 17th, the President, Sir JOHN WILLIAMS, Bart., being in the chair.

Dr. E. SYMES THOMPSON read a paper on the Climate of

Digitized by Google

Egypt. Dealing first with the journey thither, he thought the long sea route was often the less fatiguing. Invalids should land at Alexandria. A short stay at Ramleh both before and after the Nile journey should be made by those who leave England in October and return in May. The sulphur baths of Helouan were useful to those who were unequal to the social activity of Cairo. The Mena House Hotel, close to the Great Pyramid and on the edge of the desert, afforded a sunny haven for those unable to ascend the Nile. Luxor and Assouan, he said, were very warm in November. In February the temperature in the shade reaches 100° F. at these places, and January and February are the best times to be there. Invalids should be warned of the danger of chill at sundown on the Nile. Comparing Luxor and Assouan, he said that the air was drier at the latter place. The dangers of life in a *dahabiyeh* must be borne in mind, and it is often safer to travel by steamer. The hotels at Luxor and Assouan were commended. The indigenous maladies of Egypt were described. The warm, dry air was said to be of use in bronchial affections with emphysema, in case of quiescent phthisis in all stages, especially when of pneumonic, broncho-pneumonic, or pleuritic origin, and particularly when the disease follows influenza, measles, or enteric fever, and naso-pharyngeal catarrh. Hypochondria, hysteria, and neurasthenia were also benefited, and chronic cardiac and renal diseases do well in the climate; whereas, further, the electrical condition of the desert air sometimes interfered with the sleep of healthy persons, it acted otherwise on sufferers from hysteria. In conclusion, Dr. Symes Thompson drew a comparison between Egypt, the Alps, the Canaries, and the Cape.

Dr. JALLAND considered that Assouan afforded the best climate in Egypt. The cold weather in Cairo lasted from four to six weeks, but was less higher up the Nile. At Assouan the land was not cultivated, and the inundations of the Nile were not unhealthy. It was also a clean town.

Dr. CANNEY said that dry desert air was what patients sought. In this respect Luxor had great advantages. He advocated an earlier arrival in Egypt than Dr. Symes Thompson proposed, and thought the beginning of November a good time to go there.

Dr. SQUIRE, Dr. CHAPMAN, and Dr. WHARRY also spoke, and remarks by the PRESIDENT terminated the proceedings.

BRITISH GYNÆCOLOGICAL SOCIETY.

A New Method of performing Abdominal Hysterectomy.—Exhibition of Specimens.

A MEETING of this society was held on Oct. 10th, Dr. CLEMENT GODSON, President, being in the chair.

The PRESIDENT announced the death on the previous day of Dr. Thomas Keith, a distinguished honorary Fellow of the Society. This was an irreparable loss, both to the society and to the world at large. He asked the Fellows to pass a vote of condolence with the family of Dr. Keith in their sad bereavement.—Dr. ROBERT BARNES and Dr. BANTOCK supported the President's motion in sympathetic terms, and the vote was passed unanimously.

Mr. F. BOWREMAN JESSETT read a paper on a New Method of performing Abdominal Hysterectomy, with Five Successful Cases. After briefly alluding to the history of abdominal hysterectomy Mr. Jessett pointed out that the methods of performing the operation may be divided into three classes—(1) the extra-peritoneal method of dealing with the stump by the use of Koeberle's clamp; (2) the subperitoneal method of dealing with the stump after removal of the tumour; and (3) total extirpation. Objection was taken to the extra-peritoneal method on account of the high mortality after the operation, the excessive pain caused by the dragging on the stump, the length of time which must elapse before the stump separates, and finally the weakening of the abdominal walls. Many of these objections are overcome by those surgeons who adopt the subperitoneal method. But in these the mortality is high, and Mr. Jessett pointed out that, there being a space between the roof of the vagina and the peritoneum which has been laced over the floor of the abdominal cavity, if there is any oozing of blood from the flaps a large hæmatocele may and often does result, which has in many cases broken down and suppurated. Moreover, if there should be any accidental hæmorrhage no notice is given of it until the patient may be in a collapsed condition. By total extirpation of the whole organ all these objections are overcome, but it was to the method of performing this operation that Mr. Jessett drew attention and submitted certain details which he has carried into practice with satisfactory results. Hitherto operators after removal of the entire uterus with its tumour have laced or stitched the two peritoneal surfaces of the flaps together across the pelvis, thereby restoring the floor of the abdominal cavity. Difficulty hitherto has been experienced in opening up the roof of the vagina, some accomplishing this per vaginam, and others by having an assistant's finger passed into the vagina. To overcome this difficulty Mr. Jessett has had a bivalved speculum made nine inches long, which an assistant passes into the vagina when the tumour is delivered through the abdominal wound; by having this instrument pushed well home the roof of the vagina is put upon the stretch, and it is an easy matter after the anterior and posterior flaps are reflected from the tumour to cut down upon the ends of the blades before and behind and then to ligature the uterine arteries on each side. By dividing the tissues between these ligatures and the cervix the uterus and tumour are lifted out. But it was on the treatment of the flaps that Mr. Jessett laid particular stress. He contended that by lacing these across there is a large raw surface left which will, or may, be a source of septic trouble afterwards. To overcome this he proposed that long loops of silk, some four or six in number, should be passed through these flaps at their edge so that the knot is made to come out through the speculum in the vagina by catching the loop in a specially made instrument. When all these loops are passed they are drawn taut, and the peritoneal flaps are in this way everted and doubled upon themselves into the vaginal roof. The vagina is then packed with strips of iodoform gauze, the speculum withdrawn, and the abdominal wound closed. All the patients on whom Mr. Jessett has performed this operation have convalesced easily and well, in fact just as after an ordinary ovariotomy or vaginal hysterectomy. Mr. Jessett read short notes of five cases in which he had operated successfully by this plan. The chief points in this operation are—(1) the use of the long speculum passed up the vagina, by means of which the uterus is somewhat lifted up and the roof of the vagina put on the stretch, which enables the operator to cut with precision into the vagina from above; (2) the treatment of the peritoneal flaps—by everting and drawing these down through the vagina the two peritoneal surfaces are brought into accurate apposition, and by being doubled on themselves raw surface is apposed to raw surface, and also free drainage is established at the lowest point of the abdominal cavity, through the vagina if required; (3) the flaps, being drawn down in this fashion, form a plug to the roof of the vagina, and the floor of the pelvic cavity is much firmer than if the peritoneum is simply laced across—moreover, by this method a large raw area is left, which is much more likely to cause suppuration; (4) by removing the whole uterus in this manner there is very little hæmorrhage and no need for the use of elastic ligatures or other means for constricting the neck of the tumour; and (5) the patients suffer no more pain or inconvenience after the operation than after an ordinary ovariotomy. There is no dragging on the stump, and the abdominal wound is not dragged in afterwards as in those cases which have been treated by the serre-nœud.—The PRESIDENT thanked Mr. Jessett in the name of the society for his valuable and interesting paper.—Dr. PURCELL said the chief difference between Mr. Jessett's method and that of Martin of Berlin was that the former opened the vagina from above, while the latter worked from below. He called attention to the great advantage of Trendelenberg's position for this operation.—Dr. HEYWOOD SMITH testified also to the convenience of Trendelenberg's position. He asked Mr. Jessett whether an ordinary glass speculum would not answer as well as the special one as a guide for opening into the vagina, and also what was the special indication for a drainage-tube in these cases.—Mr. TAYLOR expressed his indebtedness to Mr. Jessett for the work he had done. It seemed to him, however, that no one method could be of general application; for instance, there were cases where the inversion of the broad ligaments would answer as well as the formation of anterior and posterior flaps. Dr. Purcell was mistaken in supposing that Martin always adopted one method.—Dr. BANTOCK said Mr. Taylor had in great measure expressed his own ideas. The operation in future would rest between

Digitized by Google

extra-peritoneal treatment of the stump and total extirpation.—After some remarks by Dr. LEITH NAPIER, Mr. JESSETT replied.

Mr. E. TENISON COLLINS (Cardiff) showed a very large Spleen removed post mortem. During life it was thought to be an ovarian tumour. Abdominal section showed its true nature. The medical attendant who was present would not sanction its removal, so the abdomen was closed without proceeding further. The patient, however, died the same evening from shock. No hæmorrhage was found at the necropsy.—Dr. HEYWOOD SMITH had lately had a case sent to him as an ovarian tumour, but examination showed it to be the spleen. He asked Mr. Bland Sutton to see it with him. Mr. Sutton advised removal and performed the operation. The patient made a good recovery.—Mr. H. B. GARDNER and Mr. J. W. TAYLOR spoke on the subject, and Mr. COLLINS replied.

Mr. J. W. TAYLOR (Birmingham) showed a large Uterine Myoma removed by Abdominal Pan-hysterectomy. Operation was urgently required on account of hæmorrhage. The shape of the tumour rendered the use of the clamp impossible or dangerous, and oöphorectomy would have been useless. He decided upon total extirpation. After separation of the tumour laterally by ligatures placed outside the ovaries and tubes, the bladder was dissected off anteriorly and the vagina was opened anteriorly and posteriorly. The remaining attachments were temporarily clamped whilst the tumour was lifted out. The patient did well and was discharged three weeks after the operation.

Mr. R. H. HODGSON showed a specimen of a large and partially solid Ovarian Tumour. The evacuated fluid portions measured three quarts and the remaining solids weighed four pounds. The patient made a good recovery.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY.

The Pathology of Certain Forms of Vesical Tumour.

A MEETING of this society was held on Oct. 10th at the Great Northern Central Hospital, the President, Mr. CHARLES KING, in the chair.

An address was given by Mr. J. H. TARGETT on the Pathology of Certain Forms of Vesical Tumour, which was copiously illustrated throughout by lantern slides prepared from photographs of the actual specimens. Mr. Targett discussed in the course of a most valuable address, not only the pathological appearances of the forms of tumour selected for the demonstration, but also their clinical recognition and modes of treatment. The first group of preparations illustrated the appearances of certain large single sacculi connected with the urinary bladder by narrow orifices. Much interest was especially taken in the description of sacculi occurring at the lower part of the bladder in the region of the trigone and probably the result of failure in the proper development of this region. Methods for the recognition of these sacculi during life were suggested, and the complications which arise owing to their growth were referred to. In certain cases the possibility of their removal was discussed, and operation was considered to be advisable by the speaker. The second variety of tumour brought forward was the recto-vesical hydatid cyst. It was shown that the cyst originated in close relation with the bladder walls, in fact in the muscular or fibrous coats, and that, therefore, the usual statement made in the text-books that they were found in the pelvis, having gravitated from the liver or some other situation in the abdominal cavity, was quite erroneous. The operative treatment adopted by Mr. Bond for this class of tumour was recommended and explained. The remaining preparations dealt with some of the important forms assumed by solid tumours of this region and the complications that they may bring in their train. Some exceptionally beautiful preparations were shown of the villous papilloma with all the epithelium *in situ*. In connexion with these the speaker mentioned the difficulty of recognising shreds of such papillomata in the urinary excretion. The most that might be expected to be observed was the very delicate fibrous strand forming the "core" of one of the villous processes. Even should this be found the diagnosis as to whether the tumour was malignant or not was in no degree advanced, for such a complication as the occurrence of an apparently benign villous growth covering or depending from a carcinoma is at times met with. The modes of extension of malignant growths formed a very interesting section of the demonstration. The last subject touched on was the possibility of the ureters becoming prolapsed and simulating polypi.

NORTH-WEST LONDON CLINICAL SOCIETY.

Exhibition of Cases.—Demonstration of Apparatus.

A CLINICAL meeting of this society was held on Oct. 16th, Dr. W. K. SIBLEY being in the chair.—Mr. JACKSON CLARKE showed a case of Aural Polypus successfully treated by the Application of Alcohol.—Dr. SIBLEY exhibited a case of Exophthalmic Goitre treated with Suprarenal Extract, and one of Abdominal Aneurysm.—Dr. CAGNEY showed a child with Infantile Paralysis in whose case energetic treatment in the acute stage was successful.—Mr. JACKSON CLARKE showed a patient in whom he had effected Perineal Drainage for the relief of Cystitis, and Mr. C. P. ALLEN exhibited some cases of dermatological interest.—Dr. Boulting, Dr. Bulger, Mr. C. G. Brodie, Dr. Campbell, and Dr. Herschell discussed the cases.

Dr. HARRY CAMPBELL gave an experimental demonstration of the Pulse and Arterial Tension with an apparatus which he had devised.

LIVERPOOL MEDICAL INSTITUTION.

Villous Tumour of the Rectum.—Chronic Hydrocephalus, Trephining, Recovery.—Latent Congenital Syphilis.—Exophthalmic Goitre, with special reference to the Thyroid Theory of the Disease and the Treatment of the Affection by Operation.

AN ordinary meeting of this society was held on Oct. 17th, Dr. WARBURTON, Vice-President, being in the chair.

Mr. PAUL related the case of a woman aged fifty-six years from whom he had removed a very large Villous Papilloma of the Rectum. Symptoms of bearing down, a constant desire to defecate, and the passage of blood and mucus had existed for five years. The growth formed a broad band two to three inches deep around the rectum about two inches and a half from the anus. The patient made a slow but otherwise good recovery. The tumour had the typical structure of villous papilloma and did not infiltrate the submucous tissue. The origin of the growth could be distinctly traced to the neck of Lieberkühn's follicles, and Mr. Paul suggested that the histological distinction between the three usual neoplasms in this situation was as follows. Papilloma commenced as an upward growth of the neck of the glands, polypoid adenoma as an overgrowth of the entire glands, and carcinoma as a downward growth of the deep portion of the follicles.—Mr. RUSHTON PARKER agreed with Mr. Paul that a purely villous papilloma was not likely to become malignant. No doubt it was an extremely rare disease in the rectum, but the patient having recovered well from the operation was probably entirely freed from her disease.

Mr. THELWALL THOMAS showed a young man nineteen years of age on whom he had operated six months ago. The case had been transferred from Dr. Glynn's wards. There was a history of very severe and increasing headache, chiefly occipital, for eighteen months, extreme giddiness and ataxia, with falling to the right side. There were nystagmus, diplopia, paralysis of the right superior oblique, and marked double optic neuritis. The circumference of the head was twenty-five inches. The right cerebellar fossa was opened and the tense, non-pulsating dura mater bulged; this was opened and then the brain bulged. By exploring with the finger no tumour could be made out, but the space under the cerebellum was closed by a membrane; this was easily broken through with the finger and a quantity of clear fluid liberated. The medulla and floor of the fourth ventricle were distinctly felt. The bone was not replaced. The headache soon disappeared, and the man quickly regained all his faculties and was now apparently quite well, six months having elapsed since the operation.—Dr. GLYNN, when he suggested operation to Mr. Thomas, thought the case was one of cerebellar tumour. The patient was nearly blind at the time of the operation. It was remarkable that it should not only have been followed by temporary relief but by permanent recovery. It was possible that a posterior meningitis had been followed by adhesions between the membranes in the neighbourhood of the fourth ventricle, and so caused

Digitized by Google

chronic hydrocephalus. — Mr. RUSHTON PARKER, Mr. MURRAY, and Mr. LARKIN also made remarks, the latter two speakers suggesting that it probably was a case of cystic tumour in the cerebellum.

Dr. STOPFORD TAYLOR showed a case of Congenital Syphilis in a man aged twenty-four years. It began about four years ago as a sore on the upper lip, and this, slowly spreading, involved both cheeks, the left eyelid, the left half of the scalp, and the alveolus of the upper jaw; the nose also was completely destroyed. His present condition was best described as syphilitic lupus.

Dr. ABRAM read a paper on Exophthalmic Goitre, with special reference to the Thyroid Theory of the Disease and the Treatment of the Affection by Operation. A short description of the symptoms was given, followed by a critical examination of the various theories advanced to explain the disease. The thyroid theory was held to be the most satisfactory. Two operations—namely, partial thyroidectomy and ligature of the thyroid arteries—were thought to fulfil the conditions necessary for the relief or cure of the disease. —Dr. GLYNN was very interested in the paper, though he did not accept many of Dr. Abram's contentions. He was quite sure that mental shock was an exciting cause. He thought that many cases recovered perfectly well under medical treatment.—Dr. CARTER thought that where it was clearly indicated that the thyroid was the seat of the disease operation might do good; but he was sure that there must be many other causes for the disease besides excessive thyroid secretion.—Dr. CATON said that in future in severe cases he should recommend removal of a portion of the thyroid gland.—Mr. PAUL said he had operated on two cases for Dr. Barron. The first was only moderately severe; here he divided the thyroid isthmus. There was no immediate improvement, but later Dr. Barron reported that the case was much benefited. The second operation he performed ten days ago; this was a most severe case, and the entire right lobe, which weighed two and a half ounces, was removed. No difficulty was met with in the operation, and the bleeding was less than in the case of large adenomata. The change in the patient was most remarkable; in three days the remaining half of the thyroid was not visible, the temperature and pulse had fallen, and the exophthalmus was receding.—Dr. BRADSHAW had tried the prolonged application of an icebag to the thyroid, and also counter-irritation with red oxide of mercury ointment, but without benefit in either instance.—Mr. GEORGE HAMILTON said that in many cases goitres could not be operated upon owing to the enormous vessels and sinuses present. He spoke of a case where the whole neck pulsated violently, and the isthmus extended from the cricoid cartilage to below the upper part of the sternum; when cut down on this was found to contain large vessels like those of a cricoid aneurysm.—Dr. BUCHANAN said that the fact that the symptoms following artificial removal of the thyroid, excessive administration of thyroid extract, and the pathological atrophy of the gland seen in myxœdema so much resembled the symptoms of exophthalmic goitre strongly supported the view that this disease was the result of over-activity and excessive secretion of the thyroid gland. — Dr. LOGAN, Dr. DAVIES, Dr. GIVEN, and Dr. SHERRINGTON also took part in the discussion.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

President's Address.

A MEETING of this society was held on Oct. 10th, the President, Dr. PORTER, being in the chair.

Dr. PORTER, in his address, dealt with many of the ethical questions now agitating the profession. In reference to medical etiquette he said that it was very desirable that certain canons or broad principles should be laid down decisively, and everyone entering the profession should be required to subscribe to them. Upon such a foundation a simpler and more natural system of ethics would erect itself. He then dwelt at some length upon the necessity for a more representative form of government in the profession on similar lines to the Incorporated Law Society. He also advocated very strongly the adoption of the "one-portal" principle, both as regards the entrance examination and the tests of professional fitness. There would then be no necessity for the representation of the universities and licensing bodies, as such, upon the governing body of the profession. They would then simply confer their titles on their own terms upon those who were already qualified medical practitioners. He believed, too, that one uniform standard of examination would tend to exclude some undesirable candidates for admission to the profession. Dr. Porter then touched upon the question of the abuse of medical charities, advocating a more searching inquiry on the part of hospital authorities into the circumstances of those who presented themselves as out-patients, and suggesting that in some cases the exaction of a small charge might be advisable, though he was not in favour of admitting cases indiscriminately as paying patients. State support or State aid he was not in favour of, but thought that registration and periodical Government inspection of all hospitals, dispensaries, and similar institutions would have a very salutary effect, especially if this was accompanied by the power to close all such institutions as were considered unnecessary or administered in an improper manner. He considered that the State had a duty to perform in preventing institutions which were conducted for private and personal ends being falsely marked with a title which was calculated to deceive the public and divert support from more deserving objects. The address concluded with some remarks on the national importance of medical education and the public side of medical work, and allusion was made to the very inadequate acknowledgment on the part of the public of their indebtedness to the medical profession as a body.

Reviews and Notices of Books.

Text-book of Operative Surgery. By Dr. THEODOR KOCHER, Professor of Surgery and Director of the Surgical Clinic in the University of Berne. Translated from the Second Revised and Enlarged German Edition, by HAROLD J. STILES, M.B., F.R.C.S. Edin., Senior Demonstrator of Surgery in the University of Edinburgh, &c. With 185 Illustrations. London: Adam and Charles Black. 1895.

THE Surgical Clinic at Berne, under the superintendence of Dr. Kocher, has for many years been one of the chief centres of surgical activity and progress on the Continent. Any work on operative surgery coming from such a source ought to command the attention of surgeons, and they will find this text-book full of interest. The book contains much that is new to British surgeons and is full of valuable suggestions, and no operator can fail to gain from its careful study. But it is essentially a work for surgeons rather than for students. Compared with the guides to operative surgery with which the British student is familiar, this work is markedly lacking in those numerous details attention to which is absolutely necessary for success. A knowledge of these is taken for granted by Dr. Kocher: he has written for those who are personally and practically familiar with the details of operating, and in many cases has sketched in outline only difficult and elaborate surgical procedures. For the practised surgeon this is an advantage, but it renders the work of less use for the student. The illustrations are numerous, accurate, and drawn on a large scale, and are a noteworthy feature of the work. Dr. Stiles has done his work of translation admirably; we are able to read Dr. Kocher speaking to us in good idiomatic English.

Diphtheria and its Associates. By LENNOX BROWNE, F.R.C.S. Edin. London: Baillière, Tindall, and Cox. 1895. pp. 260. Price 16*s*.

THERE can be no doubt that in respect to diphtheria scientific opinion is undergoing a marked change; for, although there are many inexplicable facts in its etiology which require to be harmonised, and although its affinities with other diseases are more numerous than was formerly conceived, the discovery of the bacillus diphtheriæ and the proofs of its pathogenic character have done much to lend accuracy to its definition. At the same time bacteriological studies have rendered the subject more complex,

Digitized by Google

since they have largely added to the class of cases which bear a close resemblance in their clinical features to the specific disease and yet on the bacteriological test are shown to be not of its kindred. The author of this timely treatise does not hesitate to meet this problem in the most critical spirit, and he has succeeded in bringing into prominent relief the new light which bacteriology has shed on the question. It is probably too soon as yet to admit that the whole truth has been attained, and it is more than likely that many of the opinions founded on bacteriology will require modification in the future; but, as marking the standpoint at present reached, and as an endeavour to clearly expound this, his work is creditable and worthy of commendation. Starting from the definition that "diphtheria is an infectious disease due to the presence of a specific micro-organism (the Klebs-Loeffler bacillus)," he goes on to point out that this may occur in a pure or simple form, and in a complex form from the mingling of cocci with the specific bacillus—that there are forms in which the latter is absent (pseudo-diphtheria), and others in which a bacillus closely resembling it, but shorn of virulence, the chief factor. He further states that these etiologically distinct affections resemble one another in the type of inflammatory changes which are known as diphtheritic, that in all but the "false" form there is evidence of general systemic intoxication, whilst the concomitant phlegmonous and pyæmic processes, depending doubtless on the coccal invasions, may occur with equal intensity in every one of the varieties. When in subsequent pages he comes to deal with the subject of bacteriological diagnosis it will be found, doubtless to the surprise of many practitioners, that there is room for the differentiation of no fewer than twelve varieties of membranous sore-throat; but it will be reassuring to learn that only a small proportion of these are wholly dissociated from true bacillary diphtheria, and that clinical diagnosis is more often than not confirmed by the bacteriological test. Although it is of moment in prognosis, the specific or non-specific character of the inflammatory membranous exudation does not lead to material alteration in treatment, saving only as to the use of antitoxin, and this, be it noted, has to be administered as early as possible, before even time has allowed of the application of the bacteriological test, if the remedy is to exert its powers most fruitfully. In an appendix to the book the author submits the antitoxin method to a searching criticism, contrasting for this purpose two series of 100 cases of diphtheria treated at the same institution with and without antitoxin. In each series there were twenty-seven deaths, which he points out is almost exactly the average mortality from diphtheria in this country. It must, however, be objected that a thorough comparison of this character requires very complete information regarding the individual cases before a remedy appropriate only to bacillary diphtheria can be discarded. We believe that on both sides of this question there has been too much haste in drawing conclusions. Taken as a whole, this monograph is one which gives a succinct and interesting account of the disease of which it treats. The chapters on etiology and diagnosis are well planned and highly interesting. More might with advantage have been said upon the morbid anatomy, and we failed to find mention of the remarkable histological studies of Oertel, which afforded presumptive proof of the action of a systemic poison some years prior to the demonstration of the toxine. The author's advice to resort more often to laryngoscopic examination is hard to follow; his preference for lactic acid as a topical application and for biniodide over the perchloride of mercury, his description of intubation, and many another practical point will be of service to practitioners. The work, which is enriched by numerous admirably executed coloured drawings by the author, and micro-photographs of the microbes found in the different forms of the disease, will, as we have already indicated, take a prominent place in the literature of the subject, although in certain directions—e.g., that of diphtheria paralysis—it might with advantage be expanded. A word of praise is also due to the typography and production of the book, which could hardly be excelled.

Diseases of the Joints and Spine. By HOWARD MARSH, F.R.C.S. Eng., Surgeon to, and Lecturer on Surgery at, St. Bartholomew's Hospital; Consulting Surgeon to the Hospital for Sick Children, Great Ormond-street. New and Revised Edition, with 79 Illustrations. London: Cassell and Co. 1895. Price 12*s.* 6*d.*

THIS volume is one of Messrs. Cassell's series of clinical manuals, and the reader must therefore expect to have the subject dealt with from a clinical rather than a pathological standpoint. Such is the case, and the work is very largely—indeed, almost entirely—the outcome of Mr. Howard Marsh's personal clinical experience. Of pathology, of course, we read, but this is by no means an especial feature of the book. Mr. Marsh has for years taken great interest in this department of surgery and has had great experience in the more conservative methods of treatment employed. He has taken a very useful part in combating views which have from time to time been advanced advocating very general resort to operation in the early stage of tuberculous disease of joints. The line Mr. Marsh has taken is stated very fully and with some amount of reiteration in this volume. We think something would have been gained by better classification of the subjects dealt with and by the exercise of more method. The various operations mentioned might perhaps with advantage have been described with more detail. The book impresses us, however, as being full of the results of a large and ripe experience.

LIBRARY TABLE.

The Stark Munro Letters. By A. CONAN DOYLE, M.D., M.S. Edin. London: Longmans, Green, and Co. 1895. Price 6*s.*—We like Dr. Doyle better as the romanticist or the Boswell of Sherlock Holmes than in his present *rôle* of literary executor. The book, perhaps from its being made up of letters, is scrappy and *décousu*. Dr. Stark Munro's theological disquisitions are intolerably dull—as dull and pompous as those in "Hypatia" or "Julian Home"—and if these are not dull where shall dulness be found? But if the reader skips these and passes on to the pages which recount the doings of the immortal Cullingworth, for immortal he surely will be, we can promise him a rich treat. Cullingworth's really great-mindedness curiously mingled with pettiness, his sound wisdom, his charlatanry, his dash of megalomania—to use the modern jargon,—all these make him one of the most memorable characters in fiction. His walk home from his surgery through the "doctors' quarter," the while he holds at arm's-length the bag full of fees, is real comedy. By the way, we should have thought that Dr. Doyle, being a man of medicine as well as a man of letters, would have been careful to select a name which could by no possibility be likely to give pain. It seems strange that he was unaware that there is in London a well-known consultant bearing this not very common surname. For the rest, the difficulties and disappointments which every young medical man will meet with in starting practice are well described, and Dr. Doyle might do worse than reprint the work in a cheap form without the theology, and get medical schools to distribute it to deserving students as an example of how, and how not, to run a practice.

Perfect Womanhood. By FREDERICK JAMES GANT, F.R.C.S. Eng. London: Digby, Long, and Co. 1895. Price 3*s.* 6*d.*—We can confidently recommend this book to anyone who is satiated with the modern woman as portrayed in the modern

Digitized by Google

novel. Here he will find no woman with "views." Sister Eva, Violette, and Lady Teresa, it is true, look at life from different standpoints; they are all beautiful and eminently genteel, and more or less theologically sound, though we are afraid that the story of the Resurrection as written by Sister Eva would not be accepted by the School Board. The work is dedicated to Princess Helena.

Clinical Lectures on Subjects connected with Medicine and Surgery. By various German Authors. Third Series. London: The New Sydenham Society. 1894.—This volume of the New Sydenham Society contains translations of eleven German clinical lectures, each one of which repays careful study in the original. The first is by the late Professor Th. Billroth, three are by Professor Ziemssen, and one is by Dr. Erb—these alone would make the volume notable. These and all the other lectures are valuable, and the volume is worthy to rank in the excellent series published by this society. We must, however, suggest to the authorities that they should exercise greater care in the translations from the German than is shown in some of these lectures. We have come across passages which are barely comprehensible, and much that is not English—at the best German English. We are accustomed to such good work from the New Sydenham Society that we are surprised that this volume bears marks of poor translation.

Elements of Practical Medicine. By ALFRED H. CARTER, M.D. Lond. London: H. K. Lewis. 1895. 10*s*.—The popularity of Dr. Carter's book is indisputably shown by the fact that it has reached its seventh edition. It is intended as an introduction to a more extensive study of medicine, and as such cannot fail to be a help to beginners. It is not, like so many smaller text-books, a simple mass of unconnected facts, but the broad principles of the different diseases are presented to the student in a form which is pleasant to read and easily assimilated. In this edition the part dealing with diseases of the skin has been written by Mr. Malcolm Morris. At the end of the book is an index of therapeutics which includes many examples of standard prescriptions which will afford a guide to the student for future work and his own modifications, which can only be made as his experience extends. There is no doubt that the present edition will obtain all the popularity of the former ones.

The Lumleian Lectures on Certain Points in the Etiology of Disease. By P. H. PYE-SMITH, M.D., F.R.S. London: J. & A. Churchill. 1895. 7*s*. 6*d*.—The Lumleian Lectures on the Etiology of Disease were delivered by Dr. Pye-Smith in 1892 and form one of the most carefully considered *résumés*, combined with a rare amount of original observation, now to be found in medical literature, and the medical profession will welcome a reprint of the same in book form. A long notice of the work is not necessary, as the lectures were commented on soon after their delivery. In the first lecture Dr. Pye-Smith considers the natural history of disease, external causes, effect of cold, contagion, and the invasion of bacteria and animal parasites. The section on the physiological origin of diseases embraces a large and important group of diseases, having their cause in physiological disturbance, gradually becoming more frequent, and ending in permanent structural disease, such as repeated errors in diet, both as regards its nature and the mode of taking meals, habitual constipation, overwork, mental and physical, &c. In the second lecture the author draws especial attention to the statistical method of inquiry and remarks that statistics, to be of value, must be taken without selection, designed or unintentional, and must be made in sufficient number to compensate for accidents. In the third lecture the special etiology of various diseases is considered, groups of disorders being taken in turn. Added to the lectures are the Harveian Oration for 1893 and a Memoir of the Life and Works of Harvey taken from the author's article in the ninth edition of the Encyclopædia Britannica.

Remote Consequences of Injuries of Nerves and their Treatment. By JOHN K. MITCHELL, M.D. Philadelphia: Lea, Brothers and Co. 1895. 240 pp.—War, with all its attendant horrors, has in many cases brought about indirect results which have been of the greatest utility. A conspicuous instance of such indirect benefits is the addition to our knowledge of injuries and diseases of nerve trunks by the brilliant observations and writings of Keen, Morehouse, and Weir Mitchell whose names will be for all time connected with the subject. A quarter of a century has passed since these observations were published, and the happy idea has occurred to Dr. J. K. Mitchell to follow up the cases which were treated by his father and others during and after the war. With great patience and industry he has ascertained the present condition of about fifty patients who had been treated for contusion, laceration, or complete division of nerves. He has grouped the cases together, and with each group gives a general account of the symptoms persisting and then furnishes the actual notes of the cases. He discusses in a special chapter the regeneration of nerves, and concludes with a chapter on treatment. The number in whom definite symptoms have persisted, even where the original lesion was slight, is very striking. These effects were chiefly pain, intolerance of heat or cold, or of both, trophic changes, especially thinning of the nails and ulceration round them, glossy skin, and in one or two cases increased growth on the side affected. The book is one of interest and will be read with great delight by those who have been inspired by Dr. Weir Mitchell's "Injuries of Nerves," and it can be strongly recommended to all interested in neurology as containing a fund of information which it would be difficult to find elsewhere.

New Inventions.

THE NIGHTINGALE JACKET.

WE have had brought to our notice a new invalid jacket—the Nightingale jacket—which is manufactured by the Jaeger Company and is on sale at their Charing-cross branch, 456, West Strand. The jacket is made of undyed camel hair and is very light and warm, and in addition to these, the main requisites of a wrap for the sick-room, it can be very easily put on, for there are no regular sleeves, only an abundance of stuff which can be wrapped round the arms and secured there by buttons at the wrists. The material is pretty as well as cosy and soft, and the price is moderate, so that we have no hesitation in cordially recommending this little sick-room comfort to the attention of our readers. In their well-known undyed woollen materials the Jaeger Company have also some new wares to display, including some pure woollen sheets which might be grateful to the rheumatic patient and the sufferers from torpid circulation.

THE OPTOMETER.

THIS instrument is a simple and handy means of testing the vision and of determining the number of the glasses required. It consists of a brass stand about twenty inches in height, which supports a disc a little more than one foot in diameter, capable of rotation on an axis, the periphery of which is perforated and carries sixteen spherical lenses numbered respectively +1, +2, +3, +4, +5, +6, +7, and +8 D, and −1, −2, −3, −4, −5, −6, −7, and −8 D. Projecting from the disc there is an arm with a clip supporting a card of test types and an astigmatic clock. The arm admits of being shortened or lengthened by sliding within a tube, the distance being fixed by a screw. Between the disc and the card there is a quadrant with four perforations carrying +0·25, +0·5, +0·75, and a + and −8. The vision is tested by looking at the card through one of the glasses, that one being selected which gives the best vision, slight differences betweeen the whole numbers being determined with glasses in the quadrant. The glasses enable the refraction to be determined of all cases from −18 to +18 D. The instrument is made by the Optical Institute of London, 89, Hatton-garden, E C.

THE LANCET.

LONDON: SATURDAY, OCTOBER 26, 1895.

YEAR by year on the festival of the Physician Apostle is held the solemn commemoration of the benefactors of the Royal College of Physicians of London, a commemoration founded by him who was at once a benefactor not only of the College but of the whole human race. And so it has come to pass that the commemorative oration is less a memorial of benefactors in general than of him who founded and endowed the occasion, the immortal WILLIAM HARVEY. Dr. CHURCH, the orator for the present year, physician, as he himself remarked, "to the great hospital with which HARVEY was so long connected," took for his subject HARVEY and the Rise of Physiology in England. Before the time of HARVEY physiology was in practically the same state as it had been in the time of ARISTOTLE; but HARVEY, with his rare scientific foresight, marshalled the scanty facts supplied by the work of his predecessors, and, adding to them the result of his own patient and laborious work, placed physiology upon a really sound basis. Having proved as far as possible with the means at his disposal the circulation of the blood, he turned his attention, to quote Dr. CHURCH, "to the problem of the maintenance of the bodily heat, and disproved the accepted doctrine that the heart was the source of heat." His immediate successors, LOWER and MAYOW, carried on his researches into respiration and circulation, and though, of course, oxygen was unknown to them, showed that the colour of arterial blood was dependent on the presence of air, and accurately described the mechanism of respiration. But so slow is the course of real knowledge that even we, in our day, are perhaps more uncertain as to the means by which animal heat is maintained than we are with regard to the means by which the solar heat is kept up.

It is a common and pathetic fact that great discoverers, in whatever field, are rarely allowed to see the benefits which eventually arise from their labours, and HARVEY was no exception. AUBREY tells us that he had heard him say "that after his book on the circulation of the blood came out he fell mightily in his practice, and was believed by the vulgar that he was crack-brained, and all the physitians were against him." Dr. CHURCH exemplified this when he pointed out that HARVEY'S researches had little or no immediate effect on medicine, even SYDENHAM being uninfluenced by them, and went on to warn his hearers that while formerly physiology was a branch of medicine the positions are now reversed. "The brilliancy of modern discoveries and the vast increase of our knowledge may for a time react prejudicially on medicine. So vast is the range of subjects bearing on medicine, and so important does each appear to those best acquainted with them, that we are in danger of forgetting that the future life of the majority of those entering our profession is to be spent in ministering to the victims of accident or disease, and that SYDENHAM'S words 'the art of medicine can be properly learned only from its practice and exercise,' will always hold good"—a warning which closely corresponds with the words of Mr. MITCHELL BANKS in his recent address before the Yorkshire Medical College. "Much study," as the wise man said long ago, "is a weariness to the flesh and of making many books there is no end." The multiplicity of subjects which a student is now expected to get up prevent his applying his time to acquiring sound and accurate clinical experience. A knowledge of nucleo-albumins, toxins, and the properties of dimethyloxyquinizine is useful to an expert, but for the average practitioner it is of infinitely more value to be able to appreciate the difference between a presystolic and a systolic murmur, or to adhere to the canon that an indefinite continued fever ought to be treated on the assumption that it is enteric.

Dr. CHURCH concluded with a graceful tribute to PASTEUR, who, he said, would be placed side by side with HARVEY in the Temple of Fame. There is, indeed, much that is common between the two: both were earnest seekers after truth, in both their scientific knowledge served but to deepen their religion, both, to use the words which the older worker quoted, were fully conscious of the fact that—

> "Never yet hath anyone attained
> To such perfection but that time and place
> And use have brought addition to his knowledge
> Or made correction, or admonished him
> That he was ignorant of much which he
> Had thought he knew; or led him to reject
> What he had once esteemed of highest price."

THE past season has been somewhat notable for the number and fatality of mountaineering accidents. In both Switzerland and the Tyrol the casualties have been numerous and the loss of life and limb grave, and the question naturally arises whether one of the favourite sports of Englishmen is worth such a sacrifice. This question will be differently answered according to the varying points of view of those by whom it is propounded. The ardent mountaineer will allege that all noble sports involve an element of danger; that danger necessarily means occasional loss of life; that the disasters of mountaineering are few in comparison, say, with those of the hunting-field; and that they are in the main avoidable and due to rashness, carelessness, and wilful neglect of proper precautions. Others—and among these may even be reckoned many enthusiastic travellers—regard mountaineering as a senseless pursuit, devoid of any real motive or utility, and a wanton incurring of unjustifiable risks. The late Mr. FREEMAN, we are informed by his biographer, could not understand how any reasonable being could waste his time among the barrenness of ice and snow when he might be spending it amidst historic cities or famous battlefields. The late Dean STANLEY, one of the most persevering and enthusiastic of travellers confesses in his letters that to him the Alps were simply "huge lumps." The ancients, as is well known, saw no beauty in mountains, regarding them rather as barriers to be surmounted or bleak regions to be sedulously avoided, and, so far as we know, there is no instance of a Greek or Latin poet celebrating the delights of mountaineering. But a sport that annually engages the energies of multitudes of the hardiest and most

Digitized by Google

enterprising of English and German tourists is not to be summarily dismissed as absurd. It certainly possesses a singular attraction for many persons, and we do not think this attraction is difficult of comprehension. Pure air, magnificent scenery, healthful exercise, difficulties to be surmounted, dangers to be avoided, an end to be achieved—all these are involved in mountaineering and serve to explain its fascination.

In connexion with any sport the questions which arise are mainly three: Is it innocent? Is it enjoyable? Is it healthful? To expect a sport *quâ* sport to yield knowledge or gain is to regard it from the wrong point of view. *Dulce est desipere in loco;* we must all relax sometimes; and the arguments which are used against mountaineering would go far to condemn all forms of amusement. As regards the three questions which we have propounded, the answer to the first two is easy. Mountaineering is without doubt innocent, and in the judgment of its adherents it is inferior to no sport in point of enjoyment. The third question, which comes more directly within our province, admits of more debate. Can we regard mountaineering as in the main and for the mass of tourists a safe and healthful amusement? This is a question which cannot be answered without considerable reserves and qualifications. Mountaineering—by which we mean ascents of 10,000 or 12,000 feet and upwards—involves much strain and severe fatigue. The strain is first upon the muscular system; but it affects even more importantly the circulatory, respiratory, and nervous mechanisms. In some persons the heart seems to feel the tax most, in others the nervous system is chiefly affected. Palpitation and "mountain-sickness"—the latter in all probability a neurosis—are the two chief difficulties that beset the average mountaineer. It is clear from these considerations that mountaineering is not for everybody. There must be, first of all, a sound general physique, considerable endurance, and the capacity for prolonged and continuous effort. This goes without saying, and is so generally understood that weaklings usually steer clear of the higher peaks. But it is not at all so generally understood that a sound heart muscle—a well-developed and well-exercised myocardium—is indispensable for any considerable mountaineering feats. Hence any suspicion of structural heart disease is an absolute contra-indication for any such exploits. Further, the heart must be not only structurally sound, but well exercised and in good condition. Hence sedentary livers, who for eleven months in the year have no regular active exercise, should not employ their holiday month in mountaineering. Yachting or fishing will be much safer for such, and perhaps not less healthful. Many Alpine accidents have been the result of neglect of this very obvious rule. For similar reasons mountaineering should be eschewed by persons in middle life who have not acquired the requisite training in youth, and even those who in the heyday of their early prime delighted in the sport and enjoyed many a "crowded hour of glorious life" on some Alpine summit would do well to remember HORACE'S maxim regarding the ageing steed, and bid a timely adieu to exploits no longer suited to their years. A certain stability of the nervous system is indispensable for mountaineering, but it is difficult to say anything precise on this head. Neurotic individuals not only climb badly as a rule, but they do not benefit by the air above a certain moderate level. A certain coolness of nerve is a necessary qualification for the many ascents which involve actual danger—danger usually avoidable and seldom extreme, but not to be lightly encountered by those deficient in steadiness and self-control.

Many of the dangers of mountaineering which bulk largely in the popular imagination are either quite rare or easily avoided. Thus, snow-blindness is not at all of frequent occurrence, is almost confined to prolonged exposure to a blazing sun upon snowfields, and is usually successfully averted by the use of coloured spectacles. Bleeding from the nose and ears, which was described by the early explorers, is practically unknown—at least, to any serious extent—at the present day. Frostbite and sunburn, though not uncommon, are seldom severe. Perhaps the most frequent ground of attack upon mountaineering is its presumed perilousness. Accidents are, no doubt, frequent, but it is certainly true that for the most part they are avoidable. Their two most frequent causes are climbing without guides and climbing in bad weather, and these are quite indefensible errors. For an unpractised climber to essay a difficult peak without a guide is to court probable destruction, and climbing in bad weather is in every way to be reprehended. Impatience and neglect of well-established rules and indispensable precautions account for most Alpine accidents. For most, but not for all. There are some dangers of mountaineering which are in certain cases incalculable. Falling stones are a case in point, and avalanches occasionally occur in unusual localities, though, as a rule, their path is known and they can be easily avoided. But, as we have already said, a certain *quantum* of danger is inseparable from all noble sports, and this is true of mountaineering. It is sad that so gallant a climber as the late Mr. MUMMERY should leave his bones in some unknown spot among the Himalayas, but he lies amongst his beloved mountains, and who knows but that may have been the end which he would himself have chosen?

THE county of Dublin is about to institute an organisation for the isolation of infectious diseases, and the draft scheme has been prepared for submission to Parliament. It involves the formation of a board which in certain respects resembles the Metropolitan Asylums Board, the members of which are to be nominated by different bodies, including the corporation and the unions of Dublin. For the moment, however, we do not propose to discuss the scheme itself or the composition of the proposed board; we are rather concerned with the opposition which the scheme has met with from the Dublin Sanitary Association—an opposition which the promoters of the scheme appear to have heard of with astonishment. The opposition is assumed to have been organised at a very small meeting of the council of that Association; but, whether this be the case or not, the grounds of objection have been definitely set out, and they are worthy of consideration.

The first objection has to do with the probable cost of the scheme. But it is quite certain that, if it is right to remove infectious patients from the six or seven general hospitals and similar institutions in which such patients are now treated, this cannot be done except at some considerable

Digitized by Google

cost. The contention is that the cost would outweigh the probable beneficial effect upon the public health. This is a difficult matter for us to determine; but one thing is certain, and that is that in London and elsewhere it has been determined—and it has been decided as the result of prolonged experience—that it is worth incurring a considerable expenditure in order to gain the very end which is here in question. This objection, as applied to Dublin, is, however, at the best a mere surmise, and for more than one reason it is hardly worth discussion from a medical point of view.

The next objection implies that such isolation of the infectious fevers in separate institutions can only be necessary in the case of one disease—namely, small-pox, the infection of which has been proved to traverse "wide air spaces." This argument, however, altogether ignores the fact that other specific infections easily traverse the smaller air spaces comprised within one and the same institution, and that the abandonment of the practice of receiving scarlet fever and similar diseases in the general hospitals of London and elsewhere has been brought about as the result of the experience that such cases could not be received into the hospitals in question with safety to the other patients. It is not a fact that small-pox is alone in question here, and hence we cannot endorse the attitude of the Sanitary Association in this respect.

The third objection which has been formulated is to the effect that the proposed scheme would very injuriously affect the interests of the Medical School of Dublin by interfering with the teaching of the infectious fevers and of their treatment by the clinical physicians of the city, and that in this manner obstacles would be thrown in the way of students. This, we frankly admit, is a real objection. The removal of the infectious fevers from the London general hospitals has tended in the same direction; and in order to meet it as far as possible it has become necessary to require, as a condition to admission for examination for a diploma to practise, that every student should have had special tuition in this respect in a hospital especially set apart for the reception of fever patients. But the difficulty is not one that applies to Dublin alone, and we may be certain that the physicians and teachers in the London hospitals would never have consented to the removal from their hospitals of the majority of the fevers, so necessary for teaching purposes, had there not been some altogether overwhelming reason for submitting to it. That such reason existed is perfectly well known, and it is highly probable that its application is by no means limited to the English metropolis. It is suggested by the chairman of the Public Health Committee of Dublin that the resolution embodying this objection could only have been passed at a council meeting in which the medical element predominated. We know nothing as to this; but we can very well understand that such an objection would be especially appreciated by the teachers at the several hospitals. The only question is whether, in Dublin as elsewhere, the evil of reducing facilities for clinical teaching is not more than compensated for by advantages to the public and to other hospital patients, and whether it cannot be made good by other teaching arrangements.

The last objection is one which carries but little weight. It is that parents and friends would object to send their children and relatives to hospitals at a distance; for it is admitted that such hospitals must be outside the city of Dublin. The experience as to this is altogether overwhelming. The difficulty in question does arise at first when the scheme is new; but when towns and cities of the size of, or larger than, Dublin have organised proper infectious hospitals the demand for admission into them steadily increases. Some 70 per cent. of the admissions to such hospitals are children; and the percentage of patients at tender ages is, as a rule, steadily on the increase. The experience of the Metropolitan Asylums Board is to the effect that they cannot keep pace with the demands made on them by Londoners, notwithstanding the fact that they are every year obliged to go further afield in order to obtain hospital sites.

Reviewing the whole series of objections raised to the principle of providing separate hospitals for the reception and isolation of the infectious fevers in Dublin, we cannot but think that the Dublin Sanitary Association would do well to reconsider the matter in the light of the experience which is available before they finally take up an attitude of opposition to the scheme now before the city and county.

Annotations.

"Ne quid nimis."

THE METROPOLITAN HOSPITAL SUNDAY FUND.

THE subscriptions to the Metropolitan Hospital Sunday Fund have this year attained to a sum far in advance of any sum ever previously reached, and the result produced upon us is the same as that which the sight of the workhouse gruel produced upon Oliver Twist—we can only say (with due gratitude for what has been received), "Please, we want some more." And the combination of greed and gratitude is easily explained. For ten years the total sum received, while varying in its units, tens, and hundreds, had remained fairly constant in its thousands, and we had, in common with the officials of the Fund, begun to believe that the high-water mark was fixed at, say, £42,000. In good times the figure would rise, as in bad times it would fall, but this sum seemed to represent the amount which the public were prepared to give, though we have never allowed that it was quite the sum that should be expected, having regard to the size of the community and the undeniable excellence of the Fund. We had almost begun to believe that all efforts were required to bring the Fund to the point which it usually reached, and that much beyond that point it was useless to expect contributions, though a drop to much below that point might occur if the exertions of the supporters of the Fund were ever so little relaxed. The Fund, however, this year has reached the noble sum of £60,000—a leap by £15,000 in advance of the previous maximum sum. This striking proof that there is nothing constant about the figure to be expected, nothing stereotyped about the generosity of the public towards the support of our metropolitan hospitals, at once emboldens us to ask: If £60,000 this year, why not £70,000 another year? And it leads us also to look into the origin of the remarkable aggrandisement that has taken place in 1895, that we may learn its *rationale*, and apply, or assist in applying, similar methods on future occasions towards furthering the interests of a Fund whose object we have so much at heart, and with whose foundation and maintenance we can claim to have been so closely connected. The upward bound has certainly been due to the action of our contemporary the *Hospital*, a journal devoted to the

Digitized by Google

interests of our hospitals and asylums, which published this year a special appeal that resulted in securing subscriptions to the Fund amounting to no less than £18,000, and we heartily congratulate our contemporary, no less than the Fund, upon this splendid outcome of well-directed journalism. The sum so raised represents the increase of the year, for the collections in the churches and from the public at large by offertory and donation remain the same as before—hardly, indeed, reaching the figure we have set down as the decennial average. But the large sums received through Messrs. Burdett and Harris, and Messrs. Pym and Vaughan from the Stock Exchange, and the princely generosity of Mr. B. Barnato, Mr. D. Marks, "and other City friends"—as they modestly style themselves in their letter to Mr. Burdett—have raised the total of the Fund from its level, possibly becoming a dead level, to the splendid figure we have announced. And the source from which these huge donations were received suggests the method by which we must, one and all, attempt to keep the Fund in the position to which it has attained, and to avoid the retrogression that at the first glance may seem likely to occur. Mr. Burdett, the editor of the *Hospital*, is also Secretary to the Stock and Share Department of the Stock Exchange, and has been able to move that notoriously open-handed and open-hearted body of gentlemen to this extent, bringing to bear upon their sentiments and their purses the influence of personal and intimate knowledge. And this is the only way in which the Fund can be made to grow; we are not even certain that it is not the only way that it can be prevented from shrinking. Individual effort is wanted. Work ersare wanted, zealots and proselytisers. And if by chance these can be found among the men who direct the paths of journals with power among different classes, sects, and *coteries* the success of the Fund, which all allow should be unquestioned, will be assured.

UNQUALIFIED ASSISTANTS AND THEIR PRINCIPALS.

IN spite of the many warnings which practitioners have had of the danger of allowing unqualified assistants to do the most responsible part of their work, the evil still continues to call for the most anxious attention of all who represent either the public or the profession. The last case which has come under our notice is instructive on this subject—that of a carman's child seven weeks old, living in Walworth, one of twins. The other twin died at three weeks from birth. They were prematurely born. The report of the inquest on which we write is in the *Daily Telegraph* of Oct. 19th. We shall be glad if there should be any incorrectness in our version of the facts to have them corrected by the principal in the case. We gather that the unqualified assistant visited the mother in her confinement. She paid him the fee. She thought he was registered or would not have received his visits. She took the deceased child to him and he said it would not live the night. Apparently it lived some days after, but there does not seem to have been any record of the visit in the books or any attempt to have the child seen by the principal, who had to decline giving a certificate. In the case of the previous child the certificate was filled up by the unqualified assistant and signed by the principal. This confusion of duties and this use of the unqualified assistant as if he were a registered practitioner is very much to be deprecated. The deputy coroner, Mr. A. W. Wyatt, characterised it "as nothing short of a fraud on the public." He then said: "We coroners are powerless in the matter. The cases ought to be taken up by the Medical Society." We cannot help seeing some confusion of duties in these last remarks of the coroner. Why is it the duty of any medical society to take up such facts? Neither medical men nor societies exist to detect fraud on the public. On the other hand, coroners and their juries do exist to investigate the causes and the circumstances of uncertificated death. This is their very function; and it is for them to make such representations of fraud in medical attendance or in medical certification to the public authorities—the Home Office, the Registrar-General, and the General Medical Council. It is true that one or two Medical Defence Societies have, at considerable expense and trouble, brought facts of the sort disclosed in this case before the authorities. They were only relieving coroners and public prosecutors or the Registrar-General of some part of their duty. But they have been little thanked for it; and it would not surprise us to see them tire of work which should be done by others. Be this as it may, any practitioner who employs unqualified assistants to attend dying patients and allows them to pose as registered men is acting without due regard to his own interests and his own duty.

A BOARD OF GUARDIANS IN A DILEMMA.

WE alluded in THE LANCET of Oct. 5th (p. 869) to vaccination prosecutions and the report of the Royal Commission on Vaccination, and pointed out the injury which is being done by the delay of this report. The Wigan board of guardians had, owing to the prevalence of small-pox, passed a resolution that the vaccination officer should prosecute defaulters since Jan. 1st, 1895. As a consequence the anti-vaccinationists, not by any means a numerous body, were up in arms, held a public meeting, and passed the usual condemnatory resolutions in regard to vaccination, and called on the guardians to stay proceedings till the report of the Royal Commission on Vaccination was published. It was then found that when the previous resolution was passed the friends of the anti-vaccinationists on the board had been napping whilst the resolution was carried. At their meeting on Friday, Oct. 18th, a Mr. Prescott was called upon to move the following resolution, of which he had given notice—namely, "That the resolution of Aug. 23rd, 1895, passed by the board of guardians, authorising Mr. Robert Halliwell, the vaccination officer, to take proceedings against vaccination defaulters, be rescinded"—and in doing so spoke as to the cases of small-pox in the town, stating that none had occurred amongst the unvaccinated children, and that the Royal Commission had requested that all prosecutions should be withheld until their report was given. When the report was before them they could consider the question afresh. Mr. Southworth very sensibly remarked that he really could not understand why they should come there fortnight after fortnight simply to pass resolutions at one meeting and rescind them at another. One intelligent guardian stated that, as no cases of small-pox had occurred amongst the unvaccinated, "it seemed to him that if any summonses had to be issued they should be issued against those who had had their children vaccinated and thereby brought disease upon them." After a lot of empty discussion on the legality of the last resolution Mr. Clayton, an old guardian, made a most intelligent and effective speech. He remembered the resolution to stay all vaccination proceedings, but it was five or six years ago. It was a resolution that no prosecution should be taken until the Royal Commission had given their report. Since then there had been three changes of Government, and the Royal Commission had had to be appointed every time. He did not know whether they had been reappointed during the present Government, but it was evident that if they had to wait for the report of the Royal Commission they would have to wait a very long time. He was one of those who believed in vaccination, but he also believed in shaking hands with a man or woman even if he or she might happen to differ from him. When he was a young man the vaccination question was more talked about than it was in these days, for when they looked back on the history of the last hundred years and saw what had been done to overcome the terrible scourge

Digitized by Google

of small-pox they would see that now they were living in their own vineyard in comparison to the way their forefathers lived, and it had all come about simply through vaccination. At the present time the Wigan Sanatorium was full of small-pox cases, and in Aspull it was rampant, and they would stultify themselves as representatives of the ratepayers if they did not do their best in trying to continue the good work that their forefathers had done in keeping down the terrible scourge. When he went to school one child in every fifty was marked with small-pox, but it was seldom they saw one marked now. He would certainly vote against the resolution, for he believed that it was nothing but men having a few fads that had brought the question up again. Even if he had to stand by himself he would have his opinion the same as everyone else, and he would vote against the motion. Ultimately the motion was withdrawn, and the clerk was instructed to report at the next meeting on the resolution passed five or six years ago.

DEATHS UNDER CHLOROFORM.

IN the first case upon which we comment, which occurred on Sept. 11th, the patient was a woman aged fifty-four, who was admitted into the Greenwich Infirmary to undergo an abdominal section. She was carefully prepared for the operation. She was a chronic alcoholic, but physical examination revealed no organic disease. Chloroform was given from folded lint, the chin being supported by the ring finger and the little finger. Old iritis rendered the right pupil irregular; the left was observed to be small and to react to light. At first the patient held her breath, and there was some struggling. The pulse was watched, and was fairly strong and regular. Seven minutes after chloroform was commenced she ceased to talk, and conjunctival reflex went. The breathing was regular. The lint was now withdrawn and not reapplied. Immediately after this, before the operation was commenced, the breathing became stertorous and the face became livid. The tongue was now drawn forward and the chin further up, but the lividity increased, and, although artificial respiration was practised and venesection performed, the patient only gave five or six irregular respirations and then died. Inversion, cardiac acupuncture, nitrite of amyl inhalations, injections of strychnine and of ether were also tried. Two drachms of Duncan and Flockhart's chloroform were used, a little being dropped on either face of the lint alternately. The necropsy showed extensive fatty changes in the myocardium and engorgement of the viscera and meninges with dark fluid blood. The medical men present regarded the death as due to asphyxia, a conclusion which the details given above lead to. The reason for the overdose does not seem so clear. The use of lint is open to the objection that it is almost impossible to maintain an equable atmosphere of chloroform with it, as each time chloroform is dropped on the patient for the moment includes a higher percentage vapour. It is possible, if the chin had not been held up from the first stertor would have appeared earlier in the case, and so have given warning before the nerve centres had become so deeply narcotised. The name of the administrator of the chloroform is not stated. Another death is reported as having occurred under chloroform at the new Somerset Hospital, Cape Town. The patient, a man aged thirty, was admitted to have an operation performed on his finger. Chloroform was given by Dr. Hofmeyer, the assistant medical officer to the institution, after the patient's chest had been carefully examined. The operation was completed when the patient was noticed to be breathing badly. Half an ounce of chloroform was given from "a mask held near the face." The patient struggled a good deal in going under. When respiration grew embarrassed the pupils dilated and the face grew livid. The post-mortem appearances of fatty visceral changes were present. It was thought that the death was due to syncope. A battery was used over the precordial region and artificial respiration kept up for a time. This case resembles the one given above, and appears to be one of asphyxia—probably in each case the stage of struggling led to the intake of an overdose of chloroform. The third case we have already briefly noticed, but further particulars have since reached us through the courtesy of Mr. Richard Coates, the house surgeon at the Newport Infirmary. The patient, a man aged forty-seven, was admitted for the performance of a trivial operation on his finger. He had previously taken chloroform well for a similar operation. Having been duly prepared and physical examination showing him free from valvular disease of the heart, although the heart's action was weak, he was given chloroform by dropping it continuously on a towel rolled into a cone. The man was very nervous and apprehensive of the anæsthetic. After two minutes of inhalation he struggled, and an opisthotonic spasm occurred lasting half a minute. During this time no air entered the chest. When the spasm had passed, chloroform was again given, but with great caution. The breathing was now quiet, and the corneal reflex disappeared. The bandage was removed from the hand, when the man suddenly grew pale and then livid. The tongue was drawn forward, the mouth being kept open by the use of a gag, and the head depressed. Artificial respiration was commenced at once, and maintained for three-quarters of an hour, while nitrite of amyl inhalations were given. Air entered the chest freely; the pupils were of medium size, but no heart movements could be detected. About three drachms of Duncan and Flockhart's chloroform were used. Death was undoubtedly due, says Mr. Coates, to "primary heart failure." The heart muscle was found to be fatty. A death under chloroform is further reported from the Oldham Infirmary. The patient, a woman aged forty-three, was admitted to undergo excision of her right maxilla for the relief of cancer. The patient was examined and nothing found which was held to contraindicate the giving of chloroform. The gentleman who was acting as junior house surgeon, gave chloroform, first from lint and then through a nasal tube (catheter in nostril) attached to Junker's chloroform inhaler. Conjunctival reflex had disappeared when this change was effected. The operation was commenced, but the patient winced. The nasal tube was withdrawn and lint reapplied, but it was noticed that the patient had ceased to breath. Artificial respiration was carried on for forty minutes, and faradisation of the phrenic nerves and hypodermic injections were tried in vain. The coroner is reported to have said that while not depreciating the skill of the gentleman who gave the chloroform, he thought that in such cases an experienced surgeon should give the chloroform. Unquestionably this case is an instance of operation shock killing through an incomplete anæsthesia acting upon an enfeebled heart. The necropsy revealed marked fatty degeneration.

CAN CISTERNS BE DISPENSED WITH UNDER THE CONSTANT SERVICE?

THIS was the question which the metropolitan medical officers of health met to consider on the 11th inst., and which, despite the passing of a resolution by a small majority, was left practically unsettled. Dr. Dudfield had ascertained that cisterns were retained in Edinburgh and Liverpool, but were dispensed with or deemed unnecessary in Dublin, Glasgow, Manchester, and Birmingham, though he and Dr. Sykes, while they would have all draw-off taps affixed to the main, were of opinion that it would be unsafe to do so without a cistern for feeding the

Digitized by Google

water-waste preventers in closets, the kitchen boilers, and the hot water service. This, however, was but a side issue, the question being the necessity of some reserve in the event of interruption of the supply through scarcity of water, accident to the mains, or necessary repairs. The essential merit of the constant service is that it provides at all times pure cold water direct from the mains, without the chance of contamination incidental to imperfectly covered and mostly ill-placed cisterns, and the retention of the ordinary cistern completely neutralises this advantage. But, while the possible contingency of the deprivation of this necessity of health and comfort—which, in the absence of cisterns, follows the suspension of the supply even for a few hours — can be averted only by maintaining a reserve of water in the dwelling, the use of that which had been stored in a cistern resorted to only at long intervals would be worse than the evils of the old system, and it would be impossible to prevent such water from being employed for dietetic purposes, the most urgent of all. The best, if not the sole, solution of the difficulty would, we think, be found in the provision of a new form of cistern, capable of holding a quantity sufficient to tide over the interval, but so constructed as to exclude alike the possibility of the entrance of dirt and vermin, and the accumulation of any deposit from the water itself. These conditions would be fulfilled by a cylinder having its bottom in the form of an inverted cone, to the apex of which the service pipe should be connected, and the whole surmounted by a lid so fitted and sealed as to be practically air-tight save for a small air vent in the cover. A cylinder 2 ft. by 5 ft., with an additional foot for the cone, would hold 100 gallons, and, if 3 ft. in diameter, 230 gallons, without risk of overflowing. These quantities would allow from ten to twenty gallons per head for a large household, and would be supplied whenever, as was done in East London throughout the recent scarcity, the water was turned on for a couple of hours each day, while constant renewal would keep the water always fresh. At the same time a draw-off tap connected immediately with the rising main would furnish water for drinking purposes perfectly fresh, and in hot weather colder than that from the cistern, which, as well as all pipes, ought in every case to be fixed where they cannot be affected by frost. Nothing can be conceived more irrational or worse than the vast majority of cisterns fixed in the most absurd positions on or under roofs, under floors or ceilings, even in waterclosets, covered, if at all, with loosely fitting boards cut away for the entrance of the supply pipe (which might just as easily be soldered into the side), and nearly always difficult of access for inspection or cleaning.

PAST v. PRESENT METHODS OF TEACHING.

THE address of Mr. Mitchell Banks before the Yorkshire College Medical Students' Society upon present methods of teaching as compared with past may well cause many who read it to ask themselves, "Are we so much better than our forefathers?" We have no desire to pose as reactionaries, but we must agree with Mr. Banks that a modern medical student is required to get up an enormous mass of material which is absolutely useless to him in his profession. "Botany and zoology," said Mr. Banks, "I would cut clean out of the medical course." It is impossible for any student to learn thoroughly all the subjects he is supposed to learn. The medical curriculum now embraces as many subjects as the School Board teach, and the result in many cases is equally useless. The average student knows all about the nerve to the stapedius or the course of the pneumogastric, but he cannot or does not realise why dyspepsia simulates heart disease. He heaps together a quantity of dissimilar facts, but fails to draw any deduction from them. We remember being once asked by an enthusiastic and hard-working student: "Can you tell me the microscopic appearances of the lymphatics of the rectum in an early stage of carcinoma." Having confessed our ignorance, we showed the inquirer a well-marked Pott's fracture, and said, "What's this?" "Oh, that!" he said, "that's talipes equino-valgus." Now it is this kind of diagnosis that we fear modern methods have rather a tendency to produce. The knowledge may be there, but the art of applying it is wanting. We can only hope that Mr. Banks's address will go some way towards making modern education less theoretical and more practical.

FRENCH COLONIAL MORTALITY.

M. LAGNEAU, who is admitted to be a competent authority on the subject, has recently written an important article dealing with the sickness and mortality of French soldiers on foreign service, which has been published in *La France Militaire*. It seems that although the most ample sanitary statistics are issued regarding the land forces on duty in France itself, as well as in Algeria and Tunisia, there are no official documents whatever from which similar information can be obtained with reference to the remainder of the stations that are garrisoned by French troops, and inquirers seeking for enlightenment on this head are obliged to depend upon private sources of information. Under such circumstances it is naturally very hard to arrive at an exact appreciation of the actual state of affairs, and the complexity of the question is still further added to by the exceeding difficulty of ascertaining the ultimate fate of the numberless invalids who are sent to their homes on account of maladies contracted while abroad. In default of accurate figures, M. Lagneau, after considerable research, has satisfied himself of the approximate accuracy of the subjoined table, which represents the military mortality per 1000 of strength at the stations named:—

France	7·00
Algeria	11·16
Tunisia	12·20
New Caledonia	8·30
Martinique and Guadeloupe	50·00
Guiana	237·00
Tonkin	77·00
Cochin China	21·00
Réunion	29·00
Madagascar (1880)	75·00
Senegal	74·00

The following extracts from M. Lagneau's paper are interesting: "Madagascar, with which we are so occupied at present, is remarkably insalubrious. 'What an army corps,' exclaims M. Planchut, 'could we not form with the soldiers and marines who gradually, one by one, have been overthrown by fever?' Dr. Guiol, who remained four years at Nossi-Bé, where thirty-nine principal medical officers succeeded each other during forty years, has left it on record that the annual mortality amongst civilians is 89 per 1000, and amongst the military 75 per 1000—proportions which lose nothing of their gravity when we remember the numbers that are sent to die at Mauritius and Réunion. ..... The troops most affected by colonial residence are the marine infantry. Taking part in all the expeditions to unknown territories, occupying in a more or less permanent fashion the most unhealthy posts, these soldiers too often contract diseases to which they succumb either before or after their return to France. According to Dr. Lutaud, out of 1000 marines 18·9 die annually in France, 31·2 in Martinique, 34·5 in Guadeloupe, 140·6 in Senegal, 28·5 in Réunion, 28·1 in New Caledonia, and 97 in Cochin China. The average mortality in this branch of the military service would seem to be 70 per 1000

Digitized by Google

for the rank and file and 90 per 1000 for the officers." In conclusion, M. Lagneau eloquently calls for the regular publication of exhaustive information on all points that concern the health of the soldiers serving in foreign climes. "By the side of victories, of expeditions, of conquests, and of territorial acquisitions should appear the expenditure, the sacrifices, the victims entailed by these achievements. The nation which supplies the men, the Parliaments which decide for peace or war, the Governments which order the occupation of a district, the generals or admirals commanding the forces, all are interested in knowing the mortuary dime exacted by each war, each campaign, each territorial acquirement. For in our country, more rich than populous, it behoves us to be economical of human lives."

THE COUNTY COUNCIL AND THE LONDON WATER BILLS.

THE discussion at the meeting of the London County Council on Tuesday last on the question of the purchase of the undertakings of the London water companies took an important and interesting turn. It will be remembered, as was reported in our issue last week, that an amendment that the Bills for the purchase of the London water companies should be proceeded with, was lost by a majority of one only. This amendment was opposed to the recommendation of the Parliamentary Committee that the Council "do invite Her Majesty's Government either to deal with the question themselves or to appoint a Royal Commission to do so." This recommendation being approved by the small majority of 1, amounted to a decision not to proceed with the eight suspended water Bills. As, however, the Council have expressed a desire that they should be the water authorities for London, Dr. Collins proposed an amendment, on the debate being continued this week, that the matter should be referred to the Parliamentary Committee to report to the Council without delay the lines on which they suggest that the Government should be asked to legislate. This just and sensible proposal was carried by a majority of nine, so that in the event of the Government being asked to deal with the question they will, as Mr. J. Stuart, M.P., observed, at least have an outline presented to them of the course to be pursued. This, we hope, will lead to some very definite and distinct proposals being made, so that, after all, there is promise of the decision last week to abandon the Bills being annulled pending the report of the Parliamentary Committee.

INFANT CRIMINALS.

AN inquest was held recently by Mr. Troutbeck on the body of an infant four months old whose death was shown to have been caused by her little sister, three years old, who apparently from jealousy had stuffed the child's throat with paper. This must have been stuffed into the infant's pharynx with great force, as quite a large quantity was found lodged there when she was taken to Charing-cross Hospital. The child admitted that she had done it, and there seems to be very little doubt that she deliberately meant to get rid of an unwelcome rival. She had previously shown signs of jealousy, and had pinched the infant in a vindictive way and shown her feelings so decidedly that the mother seems to have had some misgiving as to the safety of leaving the two children together. This early development of jealousy and consequent spiteful conduct, and the expression of it in the form of deliberate murder by a child three years old, are fortunately rare. It is impossible from the facts adduced to say how far this may have been the outcome of a defective mental condition, and how far to absence of self-control traceable to faulty training or other circumstances of environment, but the case deserves to be pondered over by those who are responsible for the training and care of children. Much valuable work has been done by Baldwin, Preyer, and others on the physical and intellectual development of children, but their moral development is a field for research almost untilled. The development of the passions, the growth of self-control, and the way in which healthy development is modified or checked by environment or by physical health are subjects on which accurate observations are much needed. Further, in the case of children of tender years who, without regard for ulterior consequences, commit deeds that in older persons would be criminal it is most important to know what will be the future developments of character. It certainly does not indicate the same amount of inherent criminal tendency when an infant performs or attempts murderous acts as when an older boy or girl like the Plaistow lad deliberately kills another person. What is wanted is careful observation of a large number of children over many years. With a little coöperation much might be done in orphan schools, where children are received at a tender age and remain for some years. But a most fruitful field for investigation, the results of which would be of inestimable value to those who direct and organise education, is to be found in the ordinary private and public middle-class schools of the country. With the help of the medical officers of the schools forms might be devised so that the parents might give the necessary information as to the early moral as well as mental development of the children. This could be entered in a register, and every term the development of the boy or girl under observation could be added, with any striking instances in which particular moral traits had been exhibited. By such collective investigation much may be learned, and we may be able to judge from characteristics shown by a child in what way he will tend to develop, so that his education and his surroundings may be suitably selected. This need has made itself felt in the scholastic profession. The College of Preceptors has recently instituted a training college for masters of middle-class schools, and has arranged that one of the courses, given by a physician, shall include instruction in the observation of children with regard to the development of their faculties, both intellectual and moral. Such observations, carefully made and accurately recorded, cannot fail to produce extremely fruitful results, and it is to be hoped that the example of the College of Preceptors will be followed by other institutions which undertake the training of teachers.

LIQUID AIR, A COMMERCIAL COMMODITY.

TIME was when many of our present articles of commerce and trade were mere scientific curiosities such as only the research chemist was privileged to see, and even then under some difficulty. The tendency of the present age, however, is to turn every new scientific discovery to practical utility. Few could have anticipated the manufacture on a large scale of the complex organic compound benzoyl-sulphonic-imide, which is obtained after a long series of operations which at first were only of interest from a theoretical point of view; but yet saccharin, as it is better known, is now an important article of commerce, familiar to everybody as possessing many hundred times the sweetening power of cane sugar. Solid carbonic acid or carbonic acid snow, to give another example, was not long back viewed in comparatively small quantities with a feeling of awe and wonderment as an interesting specimen of the control which the chemist possessed over some of nature's forces. Now immense quantities of it are made chiefly for aerating beverages, and there are few of us who are not acquainted with the "steel tubes" which contain hundreds of gallons of the "liquid gas" which by the cold produced by its own

Digitized by Google

evaporation condenses to a beautiful white solid. Practically in the same way it is announced that liquid air is now being obtained in commercial quantities. It was only a few years ago that Professor Dewar produced liquid air in any substantial quantity by his ingenious device of a vacuum-jacketed vessel. The intense cold was effected by a series of operations in which liquids of increasingly lower freezing points were successively employed. For the manufacture of liquid air on the large scale which has recently commenced in Germany the employment of intermediate cooling agents has been dispensed with, the cooling effect being obtained by the rapid evaporation of the product itself. Apart from the production of a powerful refrigerating appliance, the process promises to become one of commercial importance, since as the stages in the liquefaction of the air advance it becomes richer in oxygen, until a gas is obtained containing 70 per cent. The oxygen may be further purified, if required, from the nitrogen, of which the gaseous balance, it is said, chiefly consists. As it is, however, the gas may be used in many commercial operations. We should very much like to know what becomes of the argon in this process. Perhaps at no very distant date we may come to speak of this newly discovered atmospheric constituent as an important by-product, for in dealing with the enormous volumes of air, as must be the case in the process just described, argon must be encountered in very considerable quantity, and we should not wonder if this newly known constituent of the atmosphere is eventually supplied to research students for simply the asking. As considerable obscurity still surrounds the nature of argon it is to be hoped that this new departure in manufacture may afford very distinct aid in clearing up these mysteries by placing at the disposal of investigators an unstinted supply of material. Then it would be a happy instance of science helping commerce and commerce in turn helping science.

SMALL-POX IN MANCHESTER IN 1892-94.

IN Dr. J. Niven's first annual report on the health of Manchester an interesting *résumé* of the behaviour of small-pox during the above years is given. Dr. Niven observes that when a case of this disease occurs at a common lodging-house in Manchester it is practically impossible to obtain the revaccination of the other inmates, and he doubts whether any fresh legal powers would enable it to be done. He considers that in times of small-pox prevalence the lodging-house keeper should be liable to prosecution for admitting any inmate unable to produce evidence of recent successful vaccination or revaccination sufficient for protection. Obviously this would require the laying down of some standard in the matter. Although Dr. Niven fully recognises the agency common lodging-houses play in the dissemination of small-pox, he is not inclined to attach too much importance to this means of conveyance, and he quotes from Dr. Tatham's last report on Manchester as illustrating this point: "Although this disease was prevalent through the year 1891 in many of the towns and districts of Lancashire and Yorkshire, the cases imported into Manchester during the year did not exceed two." As an instance where apparently tramps were responsible for the dissemination of small-pox in Manchester, Dr. Niven refers to the prevalence of the disease after June 1st of last year, which he considers was due to the movements of tramps through the city at the time of the Queen's visit, and in the same year there were eleven fresh reimportations of the disease. Five cases of small-pox occurred during 1894 among the fever patients at Monsall Hospital; and, in consequence of this and of the feeling that patients isolated for scarlet fever ought not to be subjected to the risks of contracting small-pox, acute cases of the latter disease were isolated at Clayton Vale Hospital. It was found necessary, however, to bring back the convalescent cases to Monsall, a proceeding which Dr. Niven believes to be free from danger to the other patients. The acute cases treated at Clayton Vale were smeared with carbolic acid in order to minimise the risks of aerial convection. In commenting upon the difficulty of diagnosing slight cases of small-pox, Dr. Niven observes that during 1894 no less than sixty-three cases were erroneously reported as small-pox, a fact which may be interpreted as meaning that the medical profession in Manchester has much trust in the sanitary authority, and does not, therefore, hesitate to report suspicious cases. Conversely, however, instances occurred where genuine cases of small-pox were not reported. Dr. Niven urges the authorities of the Manchester Medical School to take advantage of every opportunity afforded them of teaching the diagnosis of small-pox. Unfortunately, there are many students of medicine who leave hospital without having ever seen a case of small-pox, and the comparative rarity of the disease must render its practical demonstration in many instances impossible. Still, when opportunities offer they should be taken advantage of. Dr. Niven seems to have made it a practice to see each case prior to its removal to Clayton Hospital; in other words, he acted practically as a consultant in diagnosis. If all medical officers of health had had as extensive an experience of infectious disease as Dr. Niven has, perhaps the practice might be generally adopted with advantage. The figures supplied in the report before us in regard to the behaviour of the vaccinated and unvaccinated among the cases of small-pox treated in hospital during the years 1892-94 are interesting; they relate to 996 cases. At all ages the fatality rate among the vaccinated was 4·04 per cent., among the unvaccinated 26·47 per cent., and among the doubtful 13·21 per cent. The most noticeable feature among the age groups was the absence in the vaccinated of any death below fifteen years of age. Among the unvaccinated, on the other hand, the fatality rate from birth to five years was 32 per cent. and from five to fifteen years 20 per cent. From fifteen to twenty-five the fatality rate among the vaccinated was 0·76 per cent., as compared with 21·74 among the unvaccinated and 11·11 among the doubtful. From twenty-five to forty-five the respective percentages were 6·16, 31·25, and 21·05, and from forty-five to sixty-five 9·23, 100·0 (only two cases), and 9·09. Dr. Niven includes in this part of his report an excellent memorandum as regards the investigation of cases of small-pox for the guidance of his sanitary inspectors.

BOGUS PRACTICES.

THE *Sheffield Weekly Telegraph* in a recent number gives an interesting account of the way in which a medical man may be taken in when buying a practice. It pictures the smart sporting medico who sets up on credit in a fashionable country spot and then, after a few months, advertises an advantageous opening which he (the present possessor) is obliged to give up on account of an appointment abroad. Eventually the practice is sold, and the new man finds out, all too late, that he has bought a worthless opening and is still further hampered by being unable to obtain any credit from the tradesmen around, as the gentleman who has just departed quite forgot to settle many bills. We cannot believe the swindling is carried on quite so systematically and in such a wholesale manner as represented by our contemporary, but it unfortunately cannot be denied that many unfortunate men are swindled in buying practices, and too often the deceivers do not get called to account, for the buyer, already having parted with much of his capital, dare not risk the remainder in an expensive and possibly unsuccessful lawsuit, but settles down to a struggle

Digitized by Google

for existence which may hamper him for many years. The only true remedy lies in the great care which ought to be used before buying a practice, and it is well worth while to spend a little extra in having the books and general circumstances well examined rather than risk years of drudgery, and possibly ruin, which may follow an unfortunate purchase.

NEURITIS IN PREGNANCY.

THE view of Eulenburg that many cases described as puerperal neuritis are really cases of neuritis occurring in association with pregnancy receives confirmation from a case published in a recent number of the *Deutsche Medicinische Wochenschrift* by Dr. Stembo. The patient was a young woman aged twenty-four, who, in the second month of her first pregnancy, was seized with persistent vomiting, which continued for three months. During this time there were pains in the legs and later distinct weakness in them, especially affecting the left leg. There was pain on extending the fingers, impairment of the movements in the lower limbs, atrophy of muscles in the upper and lower extremities, especially in the left peroneal region, and pain on pressure both in the muscles and nerves of the legs. There was also talipes equino-varus, the sensibility was impaired, the right knee-jerk was lessened, and the left could not be elicited. Electrical and other treatment effected much improvement, and this was considerably increased when pregnancy was completed.

THE ADMINISTRATION OF OATHS IN COURTS OF LAW.

THE approaching autumn assizes, which will be held in all but a very few assize towns and cities, induce us to refer again to the subject of the administration of oaths in our courts of law. We learn from a reliable source that in the North of England the oath with uplifted right hand, which has been the universal practice in Scotland for ages past and is now permitted in England, Wales, and Ireland by the Oaths Act, 1888, makes slow progress. Those who avail themselves of the fifth section of the Act just cited are mostly members of our profession who, having the courage of their convictions, prefer this more cleanly and solemn mode of adjuration to the uncleanly mode of assenting to the oath by handling and kissing the cover or the inside of a book which has been used for a similar purpose by a succession of witnesses or jurors. The indifference shown in the matter is very remarkable and can only be accounted for by the Englishman's veneration for ancient customs however objectionable, and the rooted dislike to any change which makes him singular. It is strange in these days of bacilli and microbes that persons who would shrink from touching with their lips a glass, cup, pipe, or anything in common with other persons should see no danger in this kissing of the Testament. When the practice commenced we have been unable, even after the most diligent search, to discover, but there are very good grounds for believing that it did not become general till the latter part of the sixteenth century. Equally unsuccessful have we been in our efforts to discover when the uplifted hand first became the form of oath in Scotland. It is evident, however, that it is the more ancient form of adjuration as well as the more universal, kissing the Book being limited to England, Ireland, and the British colonies. The form of swearing with uplifted hand has already had to fight a battle with ignorance where such might have been least expected—namely, among legal coroners, stipendiary and lay magistrates, county court judges, and even recorders. Our learned judges have not displayed such lamentable ignorance of an Act which is now nearly seven years old, though one has expressed his surprise that anyone should think he incurred a risk by kissing a Testament. Another learned judge (Justice Henn Collins) takes a very different view, having ordered a book to be destroyed after it had been handled and kissed by a witness who was infected with syphilis.[1] All the other judges have permitted the "Scotch oath," as it is often called, to be taken before them without remark. All that is necessary for a witness to do is to raise his right hand as he enters the witness-box, when the form of oath will be given him on a card to repeat, or will be dictated to him. The same rule applies to an oath taken under any circumstances and by anybody.

THE TREATMENT OF LEPROSY.

WE are glad to observe that Dr. Impey, the medical superintendent of the leper establishment of Robben Island, has arrived in Europe for the purpose of visiting the leper asylums in Norway, Russia, and Constantinople. Communications to the daily press by the ubiquitous interviewer are probably not the form which Dr. Impey would himself choose as an authoritative exposition of his views on leprosy. It is from this source, however, we learn that Dr. Impey attaches great importance to the fact, which has been long known, that under the influence of febrile and inflammatory infections of the skin, such as erysipelas and dermatitis, the local symptoms of tuberculous leprosy often disappear for a time, and that he considers that if this treatment were pushed in the earlier stages of the disease better results than have yet been chronicled might be obtained. Dr. Impey is acting judiciously in visiting the chief centres of leprosy in Europe before employing this treatment on a large scale. Although the facts on which the suggestion is made are well known, the treatment is not even mentioned in the work recently published by Hansen and Looft. Dr. Impey obtained a prize from the Royal Commission on Leprosy for an essay on the disease in South Africa, and at Robben Island he has a large number of patients under his care. It is reasonable to believe that his visit to Europe will bear interesting fruit after his return to Robben Island. The same newspaper report refers to Dr. Impey's views on the isolation of lepers, but we prefer not to take a brief newspaper report as a declaration of Dr. Impey's ideas on this important question.

CONTAGIOUS DISEASES AND INDIAN CANTONMENTS.

REFERRING to a Memorandum of the Army Sanitary Commission of Dec. 11th, 1893, regarding the prevalence of venereal diseases among European soldiers in India, we notice that the Commission, whilst fully recognising the grave character and magnitude of the evil, state that they cannot recommend the re-institution of the system of compulsory lock hospitals, mainly because the results of the experience obtained during the long time that those hospitals were in operation showed that, so far from the sanguine views which were entertained as to the reduction of these diseases by their agency having been realised, the system had practically failed to accomplish that object. We gather that had it been otherwise the Commission would not have hesitated to urge its re-establishment without delay. That the prevalence of these diseases in our Indian cantonments has gravely increased of late years and urgently calls for remedy does not, unhappily, admit of any dispute. It is alleged, however, that on a comparison between the stations in which these hospitals were closed and other places where they were in continuous operation there was a reduction of the admissions into hospital from those diseases to the extent of one-sixth only in favour of the latter. If this be so, it shows, no doubt, that the system was a relatively ineffective one. But the fact that the statistical results of the system previously in force in India have not proved as satisfactory as could be wished

[1] THE LANCET, Nov. 10th, 1894; "A Condemned Bible."

Digitized by Google

is not at all conclusive to our minds that the working of a different and better system would not be attended with different results. We hold that, at any rate, some provision is absolutely necessary to meet the requirements of the case of diseased women plying their trade to the grave danger of all who consort with them. It seems to us a violation of logic and common sense that the authorities should not have the power, as in the case of other contagious diseases, to expel women from cantonments who are known to be diseased and will not submit to treatment in hospitals provided for this purpose.

A MEDICAL APOLOGIST FOR THE ABUSE OF MEDICAL CHARITIES.

DR. THOMAS J. MOSS of New York, in the *Medical Record* of Oct. 12th, writes to refute the ordinary views held as to the frequent use of medical charities by those for whom they were never intended. His great argument is that well-dressed people are not necessarily well off. "All of these people must appear well dressed at their place of business or discharge would quickly follow." These institutions (free dispensaries) are labeled "free." "Why, then, should they advertise free treatment, and when once the patient is within the toils demand a fee?" This is either a play upon words or is playing with the intelligence of the profession and the public. Nobody denies that well-dressed people may occasionally be as poor as those who are badly dressed—in other words, nobody denies that mere dress is not a guide to the means of a patient. Nobody wishes to deny to decent, well-dressed people the help of a free or provident dispensary. Still less does anyone wish to deny them facilities for getting special help or a special opinion in special circumstances. What the profession universally, with the exception of Dr. Moss, demands is that in ordinary circumstances ordinarily well-to-do people of all classes but the poorest shall pay for medical attendance as they pay for all the other commodities of life. Ours is the only profession that accommodates itself to the means of the classes who are not rich, and yet the only one that is expected to act without due remuneration. By all means let the poor be healed in an emergency, if necessary, for nothing, but let us be sure that they are poor, and even then society and not the medical profession only should bear the cost.

AFTER the delivery of the Harveian Oration upon Oct. 18th the Baly Medal, awarded every other year to "some person who has distinguished himself in the study of physiology," was presented to Dr. W. H. Gaskell, F.R.S., the Lecturer on Physiology in the University of Cambridge. In the evening Dr. Gaskell and the Harveian orator, Dr. Church, were entertained at dinner in the College by the Fellows' Club.

AS will be seen in another part of THE LANCET the number of freshmen who have signified their intention of studying for the M.B. degree at the Cambridge University is 151, a number larger than in any previous year. At the present time there are nearly 200 students engaged in practical dissection, and the supply of anatomical material is unusually abundant.

AS we go to press the Comitia of the Royal College of Physicians of London are sitting in conclave discussing the question of the admission of women to the examination for the licentiate. There is, we understand, likely to be considerable difference of opinion among those present.

THE Sixth Congress of Medicine in Italy was opened on Tuesday last by Signor Baccelli, the Minister of Public Instruction.

THE report of the Council of the Royal College of Surgeons of England to be presented to the meeting of Fellows and Members which will be held on Nov. 7th has now been issued. Owing to press of matter in our present number we are obliged to defer publication of a summary thereof and our comments thereon until next week.

THERE have been recently three successful cases of excision of the spleen for injury at St. Thomas's Hospital. As these are, we believe, the first successful cases that have occurred in Great Britain the profession will look forward with interest to learning the details.

THE authorities of King's College, London, have arranged for the delivery of free public lectures in the theatre of the College during the winter session now commenced. The lectures will be given on alternate Mondays at 8 P.M.

DR. JOHN S. BILLINGS, director of the American Army Medical Museum, has retired from the service, and accepted the post of director of the Department of Hygiene in the University of Pennsylvania.

IN Mr. Septimus Lowe, Lincoln has lost a valued citizen, for he was for twenty years coroner for the city, only retiring from the post recently on the attainment of his seventieth year.

PROFESSOR KÖNIG of Göttingen has been chosen, we understand, to fill the post of the late Professor Bardeleben, Professor of Surgery at Berlin.

Pharmacology and Therapeutics.

VALUE OF CERTAIN COMBINATIONS OF IODIC ACID.

DR. RUHEMAN of Berlin, following up some previous researches, has shown that some of the salts formed by a combination of iodic acid with metals and with alkaloids possess a remarkable therapeutic value. This is especially the case with the iodates of silver, lithium, oxide of mercury, strychnia, codeia, hyoscine, and atropine. The first of these salts is insoluble in water, but all the others are soluble and can therefore be employed hypodermically. Iodate of silver administered internally is an excellent astringent and intestinal antiseptic, effecting a rapid cure in acute diarrhœa, chronic enteritis, and intestinal hæmorrhage. It does not interfere with the digestive functions, indeed, it appears rather to exert a favourable effect upon them. The dose is 0·005 to 0·01 gramme. Iodate of lithium was administered hypodermically in doses of 0·1 gramme in cases of uric-acid diathesis and nephritic colic. A very few injections were sufficient to stop the appearance of uric-acid deposits in the urine. This salt can also be given in the form of pills, each containing 0·15 to 0·20 gramme, to be taken three times a day. The iodate of oxide of mercury dissolves readily in water when iodide of potassium is present. The stability of the preparation is, however, uncertain. It is very suitable—in the form of hypodermic injections—for syphilis. The solution is made by dissolving 0·115 gramme of oxide of mercury and 0·08 gramme of iodide of potassium in 10 grammes of distilled water, so that a Pravaz syringeful contains about 0·01 gramme, or one-seventh of a grain of the mercury salt. The injections are somewhat painful and are only administered every second or third day. They were given with good results in twenty-four cases of syphilis in various stages. The total number required for a complete cure is stated to have been usually twenty, though occasionally thirty were needed, but the good effects very soon began to show themselves. The dose varied from that mentioned above to half as much again. The drug thus given was invariably well borne and appeared to have far less tendency than other mercurial preparations to excite stomatitis or kidney trouble. It may, of course, be administered by the mouth. Iodate of quinine may be administered either by the mouth or

Digitized by Google

hypodermically in doses of from 0·05 to 1 gramme and produces neurotonic and anti-neuralgic effects. When given hypodermically but little pain is occasioned and abscesses are never formed. Iodate of strychnine should not be given hypodermically in doses exceeding 0·006 gramme. Iodate of codeia is a much more efficient sedative and analgesic than the other salts of this alkaloid. In hypodermic doses of from 0·03 to 0·05 gramme it is very useful in neuralgia and convulsive cough, and as a substitute for morphia in the treatment of persons who have contracted the morphia habit. Iodate of hyoscine has two or three times the therapeutic effect of the hydrochlorate, the iodide, or the bromide, so that the maximum dose may be considered as 0·0005 gramme for internal use and 0·0002 gramme for hypodermic use; indeed, half this last dose is usually sufficient to produce all the effect required. In ophthalmic practice a solution of the strength of 0·05 or 0·06 per cent. may be used with advantage as a mydriatic in iritis and keratitis; it acts more quickly than other preparations of hyoscine and does not set up any irritation. Iodate of atropine in a solution of the strength of 0·5 to 1·5 per cent. is likewise an excellent mydriatic, the dilatation it produces coming on more rapidly and disappearing earlier than that caused by other salts of atropine. Another advantage this solution of iodate of atropine has is that it remains sterile for a long time and does not require other antiseptic substances to be added to it. The great physiological activity of iodates, especially that of quinine, was insisted on many years ago by Sir Charles Cameron.[1]

TERTIARY BLOOD SERUM IN PRIMARY SYPHILIS.

Dr. Viéviorovski of Moscow has made some experiments on the treatment of primary syphilis by means of blood serum from individuals affected with gummata or other tertiary forms. He was careful to select for his serum-giving subjects three persons of ages between twenty-five and forty in whom the disease had run a favourable course. The blood was obtained from the median basilic vein and was received into a vessel into which had already been placed some solution of common salt of the strength of 20 per cent. and equal in quantity to one two-hundredth part of the volume of the blood to be drawn. From this mixture the serum was prepared and examined in chemical and bacteriological laboratories, none being used until it had been proved capable of standing in a thermostat at 37·5° C. for several days without developing any mould. It was preserved in the dark and in a cool place. Five patients were experimented upon, all of whom had either hard chancres or syphilitic rash and sore-throat, no other treatment being or having been employed. The serum was injected by means of a sterilised syringe with an asbestos plunger into the cellular tissue below the angle of the scapula, the mean dose being ten cubic centimetres, and the skin being first carefully cleansed by means of ether, spirit, and carbolic acid. The injections were repeated every alternate day and gave rise to scarcely any local disturbance. Under this treatment the patients rapidly improved, feeling better and being free from pain, sleeping well and increasing in weight. The physical signs of the disease, too, showed that a good effect had been produced upon it, the chancres healing very quickly and the rash becoming less distinct. More than twenty injections were given in each case. They did not, however, appear to have much effect in preventing secondary symptoms, so that Dr. Viéviorovski is far from professing to have discovered a perfect treatment for syphilis. He thinks, however, that he has shown that the serum of the blood of persons with tertiary syphilis has some beneficial effect on primary manifestations. His observations, therefore, though they are hardly likely to be repeated in this country, have a certain value from a theoretical point of view, and he proposes to carry out further researches on the subject himself and will doubtless find some of his own countrymen to repeat them. They are, in fact, a continuation of previous observations published by Professor Pellizzari of Florence and M. Gilbert of Paris.

TRIONAL AS A HYPNOTIC FOR CHILDREN.

The *Clinical and Therapeutic Journal of Infants* recommends trional as the most prompt hypnotic for children. Given in small doses of twenty centigrammes in cachets it produces a sedative action on the brain in many cases of nervous excitement, which results in sleep being quickly obtained.

TREATMENT OF VOMITING.

In cases of vomiting Lasegne has successfully given tincture of iodine in doses of five to ten minims in sweetened water. It has been found useful in the vomiting of pregnancy. It can be prescribed with chloroform—viz., tincture of iodine, chloroform, of each five grammes—of which five minims may be taken in a little water morning and evening on taking food. It may also be prescribed with peppermint water. Creasote has also been found useful in cases of vomiting, and may be prescribed thus: creasote, oil of sweet almonds, of each five grammes; five to ten drops three or four times a day in milk.

[1] THE LANCET, June 24th, 1882.

THE ASSOCIATION OF FELLOWS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A MEETING of the committee of the Association of Fellows of the Royal College of Surgeons of England was held on Wednesday, Oct. 23rd, at 5.30 P.M., at 25, Grosvenor-street, W. Mr. Timothy Holmes, Vice-President, occupied the chair. There was a full attendance of members of the committee. The minutes of the last meeting were read and confirmed. The hon. secretary (Mr. Percy Dunn) read the following letter from the secretary of the Royal College of Surgeons in answer to a recent resolution of the committee which had been sent to the Council of the College.

"Royal College of Surgeons of England, Lincoln's-inn-fields,
"London, W.C., 31st July, 1885.

"Telegraphic address, 'Splints,' London.

"DEAR SIR,—I submitted to the Council your letter of the 22nd inst., forwarding a copy of a resolution adopted by 'the Committee of the Association of Fellows' in reference to the conduct of the business at the meeting of Fellows on the 11th inst., and in reply thereto I am directed to communicate to you the following resolution of the Council of the 11th inst.—viz.: 'That in answering Mr. Percy Dunn's letter the Council wish to point out that the meeting of Fellows was held and conducted in strict accordance with the regulations appertaining to the meeting, and that as there were no notices of motion on the agenda no discussion could properly take place, the regulations of the meeting requiring previous notice of twenty-one days.'

"I am, Dear Sir, yours faithfully,
"EDWARD TRIMMER, Secretary."

After some discussion it was decided to reply to the above letter in the form of the following resolutions, which were proposed, seconded, and unanimously carried: "1. That the Committee of the Association of Fellows regrets to learn that in the opinion of the Council the last meeting of Fellows was conducted in strict accordance with the regulations appertaining to these meetings. 2. That this regret is based upon the belief of the Committee that when the regulations for the Fellows meetings were first drawn up it was intended by their framers to give the Fellows the opportunity without definite notice (*a*) of making any observations necessary on the minutes; (*b*) of asking for any further information desired from the Council on any topic contained in the agenda; (*c*) of giving notice of motion for a future meeting, and (*d*) of discussing any of the subjects dealt with in the Council's report. 3. That, if the present regulations do not provide the opportunities referred to in the preceding resolution, the committee would respectfully suggest to the Council that the regulations should be modified in the direction indicated. 4. That a copy of the foregoing resolutions be forwarded to the secretary of the college for presentation to the Council at its next meeting."

A communication was read from the secretary of the Society of Members of the College, in connexion with which the following resolution was adopted: "That it is undesirable that the Association of Fellows should take any conjoint action with the Society of Members in regard to the resolutions which the latter body proposes to bring forward at the annual meeting of Fellows and Members of the College on the 7th prox."

It was also unanimously agreed that the question in regard to the admission of women to the examinations at the College was not one upon which the Association, as an association, was called upon to express any opinion. It was further decided not to bring forward any resolution on behalf of the Association at the ensuing annual meeting.

A resolution was passed fixing the annual general meeting of the Association for Wednesday, Nov. 13th, due notice of the same to be sent to the members of the Association.

The hon. secretary having reported that Mr. J. J. Purnell had been prevented by illness from attending the meetings of the committee, a resolution expressing the regret and sympathy of the committee was unanimously passed. This concluded the business of the meeting and the committee adjourned.

ENTRIES AT THE MEDICAL SCHOOLS.

FROM returns kindly supplied by the Deans and Registrars of the various medical schools and universities of London and the provinces, we are again enabled to place before our readers a table showing the number of students who have registered for the first time, and also of those who are at the present moment in attendance at the various institutions for the purpose of finishing their curriculum. As far as possible we have endeavoured to make the table as useful for the statistician as for the general reader, but the schools do not all follow the same plan in computing the number of students on their rolls, and this consequently detracts from the usefulness of the table in cases, where mathematical precision may be required. It will be readily perceived that some of the preliminary science students may be included in the number of generals tudents, while it is just possible that some of the general students may also be dental students, and in this way the column giving the total of the entries for the year cannot be looked upon as giving the exact number of those who have entered for a strictly medical course. Of course, the entries are in many cases not yet complete, but for London and the provinces they are sufficiently so for approximate comparison. The Irish and Scotch schools begin work at a much later date than the English; and as they have practically only just commenced the winter session the figures are not available for comparison.

From a strictly medical point of view the column headed General Students gives the most interesting figures. Comparing the total number of general students who entered the London medical schools in 1894–5—namely, 555—with the aggregate of entries for the present session (excluding the London School of Medicine for Women)—viz., 580—it will be seen that there has been a slight increase.

The schools showing the most numerical progress are the London Hospital Medical School with an increase over the figures of last year of 24, St. Thomas's Hospital Medical School with a similar increase, and St. George's Hospital Medical School with an increase of 15. The greatest fall is at St. Bartholomew's Hospital Medical School, where the general entries number 14 less than last year. This, however, is not a serious falling off when the large number who patronise this school is considered. The London School of Medicine for Women shows a record of 5 less than last year. Of the 20 new students who have entered the National Dental Hospital, 13 take the two years' hospital curriculum and 7 study for a period of twelve months. These latter are either registered medical and dental practitioners or students from the Continent.

In all but two cases—Durham University and University College, Bristol—the provincial schools individually show an increase in the number of new entries, the most marked being that of Owens College, Manchester, which records an increase of 23. University College, Liverpool, has increased its number of new entries by 15, and Yorkshire College, Leeds, by 12. Cambridge University shows an entry larger than in any previous year, 151 of the freshmen who have matriculated this year having announced their intention of studying for the M.B. degree. On the whole, no very striking record has been made by either the metropolitan or the provincial medical schools.

THE SANITARY STATE OF FULHAM.

AT a recent inquest on the body of a child, who lost his life by slipping on to the fly-wheel of a gas engine from which his father was removing the rust caused by an overflow of sewage, fresh prominence was given to a sanitary grievance which has existed in Fulham for the past ten years or more. Immediately after a heavy rain the basements of some of the houses become flooded with sewage to the depth of, in some cases, eighteen inches. After the storm is over the water subsides leaving several inches of foul smelling sediment. In the majority of instances the sewage enters the basement through the drainpipes, bubbling from the traps to a considerable height, and in one case the lid of an inspection chamber was forced off. In one house, the basement of which is covered by concrete, sewage water has forced its way through the soil, and the efforts of the occupier of the house and his builder to find the source of its entry have been fruitless.

For the past two or three years frequent complaints have been made by the Fulham Vestry, and towards the latter part of 1894 the County Council were appealed to on four occasions within a period of two months. As recently as August last they were petitioned, but no satisfactory reply has been received; indeed, the only answer which the vestry can obtain is that the Council are giving the matter their attention. Nothing whatever seems to have been done either to find out the cause or to remedy this deplorable state of things. The vestry give it as their opinion that greater pumping power is required to carry away the sewage, and some colour is given to this when it is noted that the flooding usually takes place after the occurrence of a storm on a Saturday or on a Sunday when the pumps are not at work. There is, however, another probable reason, and that is that the population has grown so rapidly that the main sewer, which eighteen years ago was large enough to serve a population of some 20,000 inhabitants, is not now of sufficient capacity to carry away the refuse of, in round figures, 100,000 people. That the evil is growing is shown by the fact that, although many of the houses have been troubled by the overflow for years, others are only just beginning to experience it. The occupier of one of the houses where the overflow has recently begun to show itself is having a brick wall nearly two feet high placed in front of his yard door in order to prevent the overflow from entering his kitchen, and another has been put to considerable expense for traps to keep out the sewage. But the evil of these palliative measures is clearly shown, for upon the removal of a floor upon which the flooding had recently taken place several inches of foul-smelling water were found beneath it. A deputation of the vestry and ratepayers has probably waited upon the Main Drainage Committee of the County Council by this time, and it is to be sincerely hoped that an epidemic of disease will not occur before the County Council take some active measures to stop such a scandalous condition of things.

THE PARIS PRISON CONGRESS, 1895.

THE Fifth Quinquennial Prison Congress recently held at Paris was well attended. Delegates from twenty-five countries were present, and for the first time Great Britain was represented officially. The President of the French Republic attended the opening sitting, and afterwards received the foreign delegates. The Minister of the Interior opened the Congress with an eloquent speech. Several other ministers also attended the meetings, and a few delivered addresses. The Congress, which met in the spacious rooms of the Collège de France, was divided into four sections, some of the principal subjects dealt with being habitual offenders, the Bertillon system, criminal insanity, intemperance and inebriate asylums, and juvenile offenders.

An animated debate took place in the section dealing with the subject of habitual offenders and cumulative sentences, and a resolution was unanimously adopted in favour of a progressive cumulation of sentences for this class of criminals, recommending also more rigorous dealing with the professional malefactor.

In the course of the discussion on the question of insane and weak-minded prisoners Dr. Motet (of T[illegible]) society in general has not hitherto been adequately protected against insane criminals or against their premature removal from asylums.

The very important questions of child saving and the treatment of criminal and neglected youth occupied a large share of the time and thought of the Congress. It was stated that in several American States the system of boarding out has been resorted to with excellent results. The children are placed with carefully selected foster-parents and are under regular supervision.

Opportunities of seeing the practical working of the Bertillon system of identification were afforded to many of the delegates, and the Congress recommended the general uniform adoption of the system as being most desirable everywhere. The members of the Congress were also granted permission to visit the prisons and reformatories in and around Paris. Considerable interest was manifested in the warders' school at the La Santé prison, where forty-eight warders from the provincial prisons come annually in two parties of twenty-four each, staying for six months, during which they receive instruction by lectures and classes in various branches of knowledge and are also taught the practical application of the Bertillon method of identification.

The Congress accomplished in the session of ten days an amount of useful and instructive work; many remedial measures were advocated, and if carried out the next quinquenial meeting will in all probability look back upon much of the work of the present Congress with satisfaction.

THE FORTY-FOURTH REPORT (WITH APPENDICES) OF THE INSPECTORS OF LUNATICS (IRELAND).

THE number of registered lunatics in Ireland on Jan. 1st, 1895, was 17,655. This shows an increase of 379 since the previous year. The inspectors repeat their views regarding this increase, attributing it as being mainly due to accumulation and to absorption of part of the mass of unregistered lunatics residing in private dwellings or wandering about the country at large.

The number of insane people of whom no official cognisance is taken appears to be large, amounting to over 22 per cent. of the whole; the statistical tables indicate that the ratio of registered insane per 100,000 of estimated population amounts to 384, while, if to this be added the number of the insane wandering at large according to the census returns of 1891, the proportion would be found to amount to 492.

Considering the overcrowded state of the existing accommodation, and notwithstanding the additions and extensions now in progress or about to be undertaken in the majority of Irish asylums, this state of affairs affords matter for serious consideration, and the inspectors appear to put it lightly when they state, "it is to be feared that this increase of the insane under care in Ireland must continue for some years to come." 3229 cases were admitted into the district asylums in 1894; of these, 2448 were first admissions. The recoveries amounted to 1309, or 40·5 per cent. of the admissions, and the proportion per cent. of deaths to the daily average number resident was 8·8. Suicide accounted for 5 deaths, and 2 serious accidents resulting in loss of life are recorded. Post-mortem examinations were held in 287 instances. This is a considerable increase on past years, but room is left for improvement. Two asylums, Richmond and Ballinasloe, are in the fore-front as regards pathological work with 66 and 62 per cent. of necropsies respectively; in nine asylums no post-mortem examinations were made. No doubt when the medical staff of these institutions is strengthened a much higher record will be established. Overcrowding is general; the sanitary arrangements of several district asylums stand in great need of improvement; fever and dysentery appear to be too prevalent. At Richmond Asylum an epidemic broke out resembling in its symptoms the Eastern disease known as beri-beri; 152 patients were attacked, and 25 succumbed. The epidemic during its whole course attacked only the insane inmates of the institution. The sanitary condition of this asylum has long continued to be a source of anxiety to all connected with the management, and it is to be hoped that the

Digitized by Google

Portrane will afford a much-needed relief in this respect. Notwithstanding the many drawbacks under which they labour and the numerous difficulties with which they have to contend, the heads of the district asylums continue to show the same conscientious and scrupulous zeal in the interests of the insane as hitherto. This is evidenced by the favourable recovery-rate, the small proportion of suicides and accidents, and the low death-rate, which compares well with that of similar and more favoured institutions in other lands.

The State Criminal Asylum at Dundrum passed a quiet and uneventful year. Several much-needed improvements have been completed and others are contemplated. The system of payment to patients for work done, which has been beneficially employed at Broadmoor for a number of years, has been introduced here and has apparently produced very satisfactory results. The tale of the insane in the lunatic wards of Irish workhouses continues to be of the same sad and depressing nature. The patients numbered 4044. The buildings are overcrowded and understaffed, the sanitary arrangements primitive, and the personal cleanliness of the inmates and the state of the bedding in many cases show much need of improvement. It is surely time that the Local Government Board awoke to a sense of their duty and responsibility towards the most helpless of the insane. A liberal measure of relief for the amelioration of the lot of these pauper lunatics ought to be provided.

There is no change in the number of private asylums. It is pointed out that in some of these institutions more comforts for the patients, increased accommodation, and suitable exercise grounds are required. The usual tables and the inspectors' reports of their visits to the various asylums are appended. These are invariably favourable to the management.

From the fulness and accuracy of this report, and the attention given to the pressing need of improvements in the surroundings and condition of the insane in Ireland, it will be gathered that considerable zeal is displayed in the Lunacy Department. It is a careful summary of a year's work and affords interesting, although not altogether hopeful, reading.

CHOLERA.

THE latest official accounts from St. Petersburg show that there has been a marked decrease in the number of cases of cholera in Russia, and, as we surmised last week, the sanitary authorities in that country are confidently looking forward to the early disappearance of the disease.

We learn from Cairo that there were two fresh cases and two deaths at Damietta on the 20th inst., while at El Menzaleh and its vicinity there were altogether thirty cases in the course of two days, twelve of which terminated fatally. Some very interesting information about Damietta, from our Egyptian Correspondent, will be found in another column.

ST. GEORGE'S HOSPITAL AND MEDICAL SCHOOL.—Considerable changes and improvements have taken place in the hospital and school during the past year. The interior of the hospital has been repainted and decorated throughout, and a reconstruction of the central block has been begun and carried nearly to completion. The reconstruction, which is not seen from the street, will provide two new operating theatres of the most modern pattern, the benches and floors being composed of marble terrazzo, and the fittings entirely of metal and glass. There are included also an extension of the chapel and board-room and a new nurses' dining-room. In the school the electric light has been installed, the arc light being laid on to all the theatres for the purpose of lantern demonstrations. The anatomical collection has been extended, a collection of surgical instruments provided for inspection, and facilities given for photographic work. Additional classes for the University of London and for the Cambridge Second M.B. work have been arranged for, and a lectureship established, for the first time in London, in Tropical Medicine. Dr. Patrick Manson is the occupant of the new chair. A valuable prize for proficiency in bacteriology has been established in the school by Mrs. Frederick E. Webb of Maida Vale, who has endowed it with the sum of £1000.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Worcestershire County Sanitary District.—Mr. G. H. Fosbroke reports that the general death-rate of the county, with an estimated population of 303,313, was for 1894 14·2 per 1000, as against 18·1 and 16·1 in 1892 and 1893 respectively. Small-pox invaded many of the urban and rural districts of Worcestershire during the period in which the disease was epidemic in Birmingham, and the city seems to have formed the focus for spreading the disease in this county. In reference to the notification of measles, Mr. Fosbroke states that his experience hitherto has tended to the conclusion that such a step reduces the mortality from the disease owing to the fact that the official visits lead to at least some sort of isolation, and thus to reduced exposure. Facilities were afforded to medical officers of health and general practitioners by the Worcestershire county council both for obtaining antitoxin for the treatment of diphtheria and also for submitting doubtful cases to bacteriological examination. Mr. Fosbroke reserves for a subsequent date a detailed report upon this subject, but he remarks in general terms that, so far as the experience of his county goes, the antitoxin treatment has had satisfactory results. Tewkesbury rural district council strenuously refuses to adopt compulsory notification. As Mr. Fosbroke observes, the fact that thirty-four out of thirty-five sanitary districts in Worcestershire have voluntarily availed themselves of the Notification Act should be sufficient to induce the Tewkesbury district councillors to give the Act a trial. Obviously, however, the councillors referred to are disinclined to admit that the mere fact of a large majority is any evidence of either the moral or intellectual rectitude of the position. In a sense we feel compelled to admire this stubborn resistance of the Tewkesbury rural district council in face of these overwhelming odds, but we think they might now capitulate without any very serious loss of dignity. To Worcestershire, as our readers will probably remember, belongs the honour of issuing the two first "orders" under the Isolation Hospitals Act, 1893, and Mr. Fosbroke states that in his county the Act has had a very beneficial effect.

Derbyshire County Sanitary District.—In the middle of 1894 the administrative county of Derbyshire had an estimated population of 444,118. Some slight modifications have taken place in certain districts as a result of the operations of the Local Government Act, 1894. The general death-rate of the county for 1894 was but 15·4 per 1000; the death-rate from zymotic diseases showed a very marked decline upon that of 1893, as also did infantile mortality. There are signs in Derbyshire of considerable activity under the Isolation Hospitals Act, and one hospital district has already been formed, while steps in connexion with another are almost complete. In the case of the Belper Hospital district, one of the urban district councils covered by the terms of the order has decided to appeal to the Local Government Board to be removed from the combination. In each of the above instances the county council has left the control of the hospitals in the hands of the hospital committee, and it has not elected any permanent members on either of the committees. Provision has, however, been made to the effect that, if the hospital committee fail within five years to erect a permanent hospital to the satisfaction of the county council, a new hospital committee, on which the county council is to elect the majority of members, is to come into existence. Dr. Sidney Barwise, the county medical officer of health, expresses a hope that future hospital committees will have larger areas under their charge, so that two or three hospitals may be erected on each area.

LONDON PORT SANITARY DISTRICT.

The report of Dr. Collingridge upon the half-year ended June 30th, 1894, which has just been issued, shows not only how well London is protected against the importation of infectious disease by sea, but also the necessity of continuing the precautions, and even of increasing the equipment at the

Digitized by Google

disposal of the port sanitary authority. During the half-year under consideration no less than 12,715 vessels were inspected, a total which shows a very material increase on former half-yearly periods. Out of this number 496 were found to be in an insanitary condition, and 455 structural alterations were carried out without any resort to legal proceedings. This latter fact is, Dr. Collingridge remarks, a sufficient indication of the real desire which exists to do what is possible to improve the lot of the sailor, and, we would add, it is an indication also of what must be the admirable tact displayed by the officers of the London port sanitary authority. There are few duties in which the personal equation is of greater importance than in the details of port sanitary administration. Dr. Collingridge thinks it would be of considerable advantage to shipowners and seamen if all plans for new vessels were submitted to the port sanitary authority for approval. Certainly it is desirable that some steps should be taken for securing the construction of all new vessels with a due regard to proper sanitary arrangements and the prevention of overcrowding. Vessels are visited by the port sanitary authority as heretofore in conjunction with Her Majesty's Customs; but there seems to have been some little difficulty in connexion with this matter in the spring of the present year. Complaints of delay to shipping arose, it seems, owing to the practice then in vogue of dealing with each ship in strict rotation, a practice which in some instances led to the detention of vessels for a considerable time. A conference between Her Majesty's Customs and the port sanitary authority was held, at which the former seemed to favour the dissociation of the combined method of inspection. This was, however, objected to, and we are glad to learn that a conference of the two authorities with the Local Government Board had the effect of solving the difficulty in a manner satisfactory to everyone concerned. Briefly put, the arrangement amounts to this:—that where it is found necessary to examine a ship and its passengers and crew in detail, such ship shall be detained until other ships awaiting inspection have been visited. In other words, "the misfortune of one vessel is not to affect all arriving at the same time." The arrangement at Sheerness by which vessels passing through the port sanitary district of London are inspected by a medical officer paid jointly by the London and Rochester port sanitary authorities continues to work satisfactorily. During the half-year under consideration 53 cases of cholera or choleraic diarrhœa were reported as having occurred on vessels during their homeward voyage, and 24 cases of small-pox were dealt with by the port sanitary officers. By-laws have been drawn up by the port sanitary authority for the prevention of nuisances from the carriage of offensive matter &c. by boat, and these when in force should form valuable additions to the means at the disposal of the port sanitary authorities for dealing with nuisances of this kind. Out of the total number of vessels inspected during the half-year 84·5 per cent. were English, 6·3 per cent. Swedish and Norwegian, 4·9 per cent. German, and 1·1 per cent. Danish. No inconsiderable amount of food was condemned within the port sanitary district during the half-year; it comprised 394 cases of tinned meats, 108 casks of salt beef, 390 carcases of mutton, 30 quarters of beef, and 10,200 packages of fruit.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6526 births and 3873 deaths were registered during the week ending Oct. 19th. The annual rate of mortality in these towns, which had been 19·4 and 21·0 per 1000 in the two preceding weeks, declined again last week to 19·1. In London the rate was 17·9 per 1000, while it averaged 19·8 in the thirty-two provincial towns. The lowest rates in these towns were 10·4 in Derby, 13·1 in Nottingham, 13·6 in Croydon, and 15·3 in Brighton; the highest rates were 24·0 in Liverpool, 24·3 in Manchester, 25·5 in Salford, 25·7 in Burnley, and 31·5 in Blackburn. The 3873 deaths included 670 which were referred to the principal zymotic diseases, against 871 and 895 in the two preceding weeks; of these, 333 resulted from diarrhœa, 107 from diphtheria, 83 from measles, 60 from "fever" (principally enteric), 47 from scarlet fever, 39 from whooping-cough, and 1 from small-pox. The lowest death-rates from these diseases were recorded in Halifax, Brighton, Croydon, Norwich, and Leicester; the highest in Swansea, Gateshead, Salford, Burnley, and Blackburn. The greatest mortality from measles occurred in Wolverhampton, Swansea, and Blackburn; from whooping-cough in Gateshead; from "fever" in Bolton and in Sunderland; and from diarrhœa in Salford, Gateshead, Burnley, and Blackburn. The mortality from scarlet fever showed no marked excess in any of the large towns. The 107 deaths from diphtheria included 76 in London, 5 in West Ham, 4 in Manchester, and 3 each in Wolverhampton, Salford, and Hull. One fatal case of small-pox was registered in London, but not one in any other of the thirty-three large towns. There were 119 cases of small-pox in the Metropolitan Asylum Hospitals and in the Highgate Small-pox Hospital on Saturday last, the 19th inst., against 234, 198, and 158 at the end of the three preceding weeks; 7 new cases were admitted during the week, against 21, 17, and 9, in the three preceding weeks. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 2838, against 2807, 2802, and 2827 on the three preceding Saturdays; 241 new cases were admitted during the week, against 339, 252, and 332 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 158 and 175 in the two preceding weeks, further rose to 215 last week, but were 114 below the corrected average. The causes of 39, or 1·0 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Bristol, Nottingham, Oldham, Newcastle-on-Tyne, and in twelve other smaller towns; the largest proportions of uncertified deaths were registered in Birmingham, Preston, Huddersfield, and Hull.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had increased in the three preceding weeks, from 17·5 to 19·3 per 1000, declined again to 18·7 during the week ending Oct. 19th, and was 0·4 per 1000 below the mean rate during the same period in the thirty-three large English towns. The rates in the eight Scotch towns ranged from 13·7 in Perth and 16·8 in Greenock to 22·1 in Leith and 22·5 in Aberdeen. The 539 deaths in these towns included 53 which were referred to diarrhœa, 13 to whooping-cough, 9 to scarlet fever, 7 to "fever" (principally enteric), 5 to diphtheria, 3 to measles, and not one to small-pox. In all, 91 deaths resulted from these principal zymotic diseases, against 96 and 94 in the two preceding weeks. These 91 deaths were equal to an annual rate of 3·2 per 1000, which was slightly below the mean rate last week from the same diseases in the thirty-three large English towns. The deaths from diarrhœa, which had been 62 and 58 in the two preceding two weeks, further declined to 53 last week, of which 20 occurred in Glasgow, 15 in Dundee, and 8 in Edinburgh. The 13 fatal cases of whooping-cough showed an increase of 2 upon the number in the preceding week, and included 5 in Glasgow and 3 in Edinburgh. The fatal cases of scarlet fever, which had been 4 and 7 in the two preceding weeks, further rose to 9 last week, of which 4 occurred in Glasgow, 2 in Edinburgh, and 2 in Aberdeen. The 7 deaths referred to different forms of "fever," were within one of the number in the preceding week, and included 3 in Glasgow and 3 in Edinburgh. The fatal cases of diphtheria, which had been 2 and 5 in the two preceding weeks, further rose to 6 last week, of which 4 occurred in Glasgow and 2 in Edinburgh. The deaths referred to diseases of the respiratory organs in these towns, which had been 98 and 97 in the two preceding weeks, declined to 92 last week, but were slightly below the number in the corresponding week of last year. The causes of 43, or nearly 8 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 21·3 and 26·8 per 1000 in the two preceding weeks, declined again to 24·2 during the week ending Oct. 19th. During the past three weeks of the current quarter the death-rate in the city has averaged 24·1 per 1000, the rate during the same period being 17·0 in London and 18·2 in Edinburgh. The 162 deaths registered in Dublin during the week under notice showed a decline of 18 from the number in the

Digitized by Google

preceding week, and included 20 which were referred to the principal zymotic diseases, against 12 and 29 in the two preceding weeks; of these, 12 resulted from diarrhœa, 4 from "fever" (principally enteric), 3 from scarlet fever, 1 from diphtheria, and not one either from small-pox, measles, or whooping-cough. These 20 deaths were equal to an annual rate of 3·0 per 1000, the zymotic death-rate during the same period being 2·8 in London and 3·4 in Edinburgh. The fatal cases of diarrhœa, which had been 8 and 17 in the two preceding weeks, declined again to 12 last week. The 4 deaths referred to different forms of "fever" were within 2 of the number recorded in the preceding week, and the 3 fatal cases of scarlet fever exceeded the number registered in any week since June last. The 162 deaths in Dublin last week included 36 of infants under one year of age, and 26 of persons aged upwards of sixty years; the deaths both of infants and of elderly persons showed a decline from those recorded in the preceding week. Three inquest cases and 3 deaths from violence were registered; and 43, or more than a fourth, of the deaths occurred in public institutions. The causes of 22, or more than 13 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

MOVEMENTS OF THE MEDICAL STAFF.

BRIGADE-SURGEON-LIEUTENANT-COLONEL DUKE and Surgeon-Captains Manders, Hayman, and Hale have embarked for a tour of service in Ceylon. Brigade-Surgeon-Lieutenant-Colonel Supple has been transferred from Jersey to Dover, and has been succeeded at Jersey by Surgeon-Lieutenant-Colonel Kirwan. Surgeon-Majors Hayes and Johnston and Surgeon-Captain H. H. Browne have embarked for a tour of service at Hong-Kong. Surgeon-Major O'Keefe has embarked for India and Surgeon-Captain Hearne for Singapore.

INDIA AND THE INDIAN MEDICAL SERVICES.

The following appointments are announced:—Surgeon-Colonel Banks to be Principal Medical Officer, Nagpore District; Surgeon-Captain K. Whitcombe to take Medical Charge of the 6th Bombay Cavalry. Brigade-Surgeon-Lieutenant-Colonel Moore, A.M.S., on return from sick leave from England, is transferred from the Mhow District to the Sind District. Surgeon-Major Lane, A.M.S., on arrival from England, is posted to general duty in the Quetta District. Surgeon-Lieutenant Rivers, on arrival from England, is posted to general duty in the Bombay District. Surgeon-Captain J. G. Hojel is appointed to act as Professor of Materia Medica and Pharmacy, Grant Medical College. Surgeon-Captain J. M. Cadell, Officiating Civil Surgeon, Etawah, is appointed to the Medical Charge of the camp of the Lieutenant-Governor and Chief Commissioner. Surgeon-Lieutenant W. Young, Officiating Superintendent, Central Prison, Lucknow, on being relieved, is appointed to officiate as Civil Surgeon, Gonda, and to hold Visiting Medical Charge of the Bahraich District. Surgeon-Captain J. J. Pratt, Civil Surgeon, is transferred from Gonda to Fyzabad, and to hold Visiting Medical Charge of the Bara Banki District. The Queen has approved of the following promotions among the officers of the Indian Medical Services:—*Bengal Medical Establishment:* Surgeon-Lieutenants to be Surgeon-Captains: Patrick Balfour Haig, Thomas William Archer Fullerton, Ralph Henry Maddox, Edward Victor Hugo, M.D., Harry George Melville, Arthur Oldham Hubbard, Charles George Robson Scott, Herbert Austen Smith, Douglas Richard Green, George McIver Campbell Smith, Hubert Malins Earle, and Joseph George Hulbert. *Madras Medical Establishment:* Surgeon-Lieutenants to be Surgeon-Captains: Pulteney Charles Gabbett and John Lewis Macrae. *Bombay Medical Establishment:* Surgeon-Lieutenants to be Surgeon-Captains: Francis Edward Swinton, Sidney Harvey Burnett, and Thomas Jackson. Her Majesty has also approved of the retirement of the undermentioned officer:—*Bombay Medical Establishment:* Brigade-Surgeon-Lieutenant-Colonel Andrew Barry, M.D.

NAVAL MEDICAL SERVICE.

The following appointments are announced:—Staff-Surgeons: J. L. Barrington to the *Astræa;* F. S. Jackson to the *Forte.* Surgeons: F. W. Stricker to the *Inflexible;* E. D. Minter, J. D. Hughes, T. Austen, and A. H. L. Cox to be lent for study at Metropolitan Hospitals.

THE CHITRAL DESPATCHES.

The telegram from Simla giving a nominal list of the officers mentioned in Sir R. Low's despatches, which was published last week, enabled us to extract the names of the several medical officers that had been included therein. The *Pioneer Mail* of the 3rd inst. publishes in a supplement the notification that has been issued by the Government of India in the military department. The Viceroy of India and Governor-General in Council takes the opportunity afforded by the approaching return to British India of a large portion of the relief force to signify the cordial recognition of the Government of India of the distinguished manner in which the force has acquitted itself during the arduous and completely successful operations now brought to a close. A letter from the Adjutant-General in India forwarding the despatch from Lieutenant-General Sir R. C. Low, commanding the Chitral Relief Force, recapitulates the operations of the force and brings to notice the services of officers and men who have specially distinguished themselves. Among the paragraphs conveying the views of Sir George White, the Commander-in-Chief in India, in regard to these services we find the following: "To the careful medical arrangements and to increased sanitary precautions may be ascribed, in Sir George White's opinion, the comparative immunity from disease and the general good health that the troops have enjoyed under very trying conditions. These results could not have been attained without the great forethought and administrative experience of the late Principal Medical Officer, Her Majesty's Forces in India, Surgeon-Major-General Bradshaw, C.B., and of the officer now filling that appointment, Surgeon-Major-General A. A. Gore; and their efforts have been well seconded by Surgeon-Colonel T. Maunsell, principal medical officer with the force, and the medical officers under his orders." Surgeon-Lieutenant D. W. Sutherland, of the Indian Medical Service, is mentioned "for the promptitude and coolness he displayed in attending on the wounded under short range fire" in connexion with the action on the Panjkora River on April 13th. Surgeon-Colonel T. Maunsell, Army Medical Staff, the principal medical officer with the force, is mentioned as "an officer of ability and experience, and his management of the medical and sanitary arrangements connected with the force has been most successful." Surgeon-Colonel Thomson, M.B., Indian Medical Service, principal medical officer, on the line of communications, is mentioned as "an officer of judgment and experience who administered his department in a very satisfactory manner." The names of Surgeon-Lieutenant-Colonel W. Donovan and Surgeon-Major G. Coutts, M.B., of the Army Medical Staff, and Surgeon-Lieutenant-Colonel P. F. O'Connor and Surgeon-Lieutenant-Colonel W. A. Simmonds, of the Indian Medical Service, are also included in the despatch. It is, of course, very gratifying to us as medical journalists to put the foregoing on record, and to notice that the military authorities in India recognise the labours of the medical service and the good work that its members have done in connexion with the Chitral Relief Force.

THE SEWERAGE OF ALDERSHOT CAMP.

For many months now the rural district council, complicated, of course, by the various local authorities, has been trying to arrange with the Government as to sanitary provision for Aldershot Camp in the matter of drainage. The suggestion was made that a sewage farm should be constructed to receive the contents of the camp drains, the ultimate disposal of the residue to be in the hands of the local authority. A draft agreement on these lines was drawn up and submitted to both parties, and it was understood that the only proposal the Government wished to put forward was that, in lieu of paying a lump sum annually for the sanitary provision, the War Office should become a ratepayer and pay upon its assessment like other ratepayers. The council paid for an assessment of the new military buildings on these suggestions being put before them, but at a meeting on Thursday, Oct. 17th, it appeared that they had been too "previous," to use an Americanism. They had stipulated that their consent to the War Office proposals should pledge them to the acceptance of no definite site for the proposed farm before the matter should have been placed before a consulting engineer to report thereon. The War Office wrote that they considered this practically a refusal by the council to proceed with the stipulations of the draft agreement, and that the question of the disposal of the garrison sewage would now be taken into

Digitized by Google

consideration by the Secretary of State. The council, after an animated debate, resolved to write to the department objecting to the construction which had been put upon their letter, and calling attention to the fact that it was the authorities' own wish, expressed in November, 1894, to become ordinary ratepayers that had determined the council to carry out the valuation, at considerable expense, of the Government property in order to bring it on the rate books. A resolution from the Portsmouth authorities suggesting the valuation of Government property on the ordinary and uniform basis was endorsed by the Aldershot council. The opinion was freely expressed that the Government department might now carry out the work independently of the latter body.

MALARIA AND ITS CAUSES.

The *Pioneer Mail* of the 3rd inst. has an interesting article on this subject, reviewing the report of Surgeon-Colonel Harvey, of the Indian Medical Service, published in the *Calcutta Gazette*, on the causation of malaria, made in connexion with the Sanitary Drainage Bill recently passed by the Bengal Government. Our Indian contemporary points out how much we still require to learn in connexion with this subject, and considers that the Government should institute a thorough and scientific investigation into the numerous questions at issue. We notice, by the way, that Surgeon-Colonel Harvey accepts the view that malarial fever is due to a parasite, in which, it may be added, he is strongly supported by the observations and researches of several medical officers who have scientifically studied the subject in India.

DEATH IN THE SERVICES.

Surgeon-General George Augustus Frederick Shelton, M.B., M.R.C.S. (retired), on the 12th inst., in his seventy-fourth year. He joined the Army Medical Service in 1845, was promoted Surgeon in 1854, Surgeon-Major in 1865, Deputy Surgeon-General in 1873, Surgeon-General in 1880, and retired on half-pay in 1882. The deceased officer served with the 48th Regiment during the latter part of the siege of Sebastopol (medal with clasp, and Turkish medal).

The London Companies of the Volunteer Medical Staff Corps will take part in the time march which is to take place in the northern suburbs of London on Saturday night next (Oct. 26th).

Correspondence.

"Audi alteram partem."

THE BIRMINGHAM LUNACY PROSECUTION.

To the Editors of THE LANCET.

SIRS,—As I am the unfortunate individual alluded to in your article on this subject—which is of vital importance, owing to the far-reaching principles involved—I must ask you to kindly insert this lengthy communication. I am sure that you must have based your accusations of my ignorance of lunacy laws and practice on the garbled reports and articles in the Birmingham press. Ever since I recovered damages for libel against one of these journals and threatened another of them they have not been prejudiced in my favour. I never personally pleaded ignorance; it would have been false, dishonourable, and disastrous for me to have done so. I was, and am, saturated not only with the Lunacy Acts of 1890-91 but also with the equally important Commissioners' and Lord Chancellor's supplemental statutory rules, besides leading cases. I had lunacy cases before, and I was not so imbecile as to trifle with pains and penalties. What I did admit in my address to the learned Recorder was that I regretted I might have misconstrued the equitable significance of two words—a pardonable error by lawyers, but unpardonable by me. I said "might" out of courtesy. I should, however, now require a High Court decision to convince me that I was wrong. None of the books you refer to decide the point.

I received a lady on May 21st. As she was only suffering from simple mania, and not, consequently, in my opinion,—I beg pardon, I am not allowed an opinion or discretion by the recent decision—"certifiably insane," I accepted her under the Act as a "voluntary boarder." I did not, therefore, require a licence, reception order, or urgency order. Before the statutory twenty-four hours for reporting to the Commissioners in Lunacy had expired a petition for an inquisition had been filed in the Court of Chancery on May 22nd. Now, if she had been "so found by inquisition," the Commissioners could not have got at me. Owing, of course, to the usual Chancery delays, they reached me through a common law quibble. The case came before the chief clerk on May 27th. He was informed that she was in my house and under my care; being satisfied, he adjourned for a further report without making any order. On June 15th I sent up an affidavit and those of two other practitioners certifying a satisfactory condition. On June 17th he was again satisfied, did not make an order, but appointed a Chancery visitor and adjourned to July 20th. In equity, if not in law, she was even now under Chancery jurisdiction. She was "pending," being so found by inquisition. But still more. The Lord Chancellor's Second Rule says that cases "pending" are the same as cases "found," and that persons acting under such conditions are to be indemnified against loss. By reason of this construction I did not keep a register of mechanical restraint, or a register of seclusion, or furnish any of the returns required in the case of Commissioners' patients, for none such are required in the case of private Chancery patients. The Masters in Lunacy do not want formalities, only general information of the patient's condition from the Chancery visitor, leaving the physician discretion in matters of treatment.

On June 26th two practitioners came on a magistrate's order and certified that the patient was not under "proper care and control." In consequence of this my patient was abducted and taken to an asylum, where she died twelve days afterwards, I believe, from exhaustion. For my construction of the two words, I was summoned on Sept. 10th for having committed six misdemeanours, which rendered me liable to twelve years' imprisonment and penalties amounting to £1800 as a possible maximum. The Commissioners in Lunacy, amongst whom were three members of the professsion, gave a fairly large order. At the Sessions I was found guilty of three misdemeanours, and fined £50. For some reason the learned Recorder was not made acquainted with the Chancery proceedings until after the verdict had been returned; that was when I addressed the court. He did not charge me with ignorance of lunacy law and rules—in fact, he appeared to agree with me. He, however, as a layman did consider me grossly ignorant of the proper medical treatment of lunatics, and had intended to have given me a term of imprisonment for having used mechanical restraint.

The patient, aged fifty-six years, suffering from simple mania, alcoholic gastritis, acute bronchitis, dilatation of left ventricle, with mitral murmur (recent), was admitted on May 21st. There were no signs of paralysis, meningitis, or ocular abnormalities, though the retinal vessels were slightly swollen. The membranes of both ears were normal. The urine was free from albumin, sugar, and casts; sp. gr. 1025. The pulse varied, according to excitement, from 85 to 120, and was fairly normal in rhythm and tension. There were no signs of vascular degeneration. She would, and was allowed to, wander about the first night and next day, followed by an attendant. On the 22nd she developed "acute mania." On the 23rd she received whole bath; temperature 100° F. She was wasted (weighed 81 lbs. nude), but very strong. She was placed in bed, and kept there by postural straps—viz., one across the chest and under the arms, which were free, the feet being kept in the centre by ankle straps, which allowed limited motion. She was confined in a barred single room, was quite unconscious of restraint, and made no effort to rise. No medicine or stimulants were given throughout. Soda water was given on first two days, afterwards 60 to 80 oz. milk, 6 eggs, and 3 oz. corn-flour, in a semi-fluid mixture, poured into the pharynx and swallowed automatically owing to inattention. The patient rapidly passed into mania gravis, and on May 29th into acute delirium. Bronchitis was relieved by inhalations, and the dilatation and murmur increased. Acute delirium not even alluded to in many text-books, and apparently not considered by those who discuss restraint. Pathognomonic signs: high temperature 102 to 104 in this case, rapid wasting, sordes, perfect incoherence, unconsciousness of environments, abolition of cerebral function, and above all, continuous restlessness, excitement, and insomnia tending to fatal exhaustion.

Digitized by Google

Treatment.—Obtain sleep (1) by forced comfortable posture in bed, of necessity (2) perfect quietude, exclusion of attendants from the room necessary, but supervise through an inspection hole in the door frequently. If not, then there are only six possible alternatives to the use of postural straps. The Recorder was told that if I had not wished to avoid expense two trained attendants in the room could have "managed" her—whatever that means—without postural straps. Granted; but I, however, wanted sleep, not "management." Alternative: (1) one or two trained attendants to hold the patient down in bed, whenever there, night and day. Objection: (*a*) this is "manual restraint," much more irritating; (*b*) the necessary noise and presence of the attendants constantly disturb the patient, whose audition and vision are hypersensitive. No sleep here. If not (1) then (2). Permitting the patient to tumble out of bed and as often replacing her, night and day. Objection obvious. If not (2) then (3). Permitting the patient to tumble about in a room "padded" or not, "trained attendants" present or not. Objection: Applicable only to cases with temporary excitement, and where the patient is rational enough to assume a comfortable posture instinctively and sleep voluntarily. In mania gravis and acute delirium such conditions are not present, consequently insomnia and fatal exhaustion must ensue. If not (3) then (4). Pack, "wet" or "dry." Objections: Wet pack must be changed frequently; inapplicable. Dry pack; a much more severe form of restraint than postural straps with the arms free. Still, the Commissioners, even in their last rules, sanction its use, but require the patient to be released every two hours. If I had used the "dry pack" and disturbed according to their rule, I would have killed my patient and got two years—not a quarter enough for my barbarity. In the Holloway case they very properly did not disturb. No prosecution followed. The learned Recorder was horrified, and fined me £50 because I allowed the patient to remain in one position for sixteen[1] hours and did not get her up more than twice a day for natural purposes, but as she had no sense to respond to calls of nature I never knew when to disturb her and get her up. If not (4) then (5). The "protection bed." This is somewhat like a coffin I have seen used abroad. Objection: As the arms are wholly confined it is much more severe than the postural straps. Although recommended by eminent English authorities I would have got about twelve months additional if my patient had died in it. If not (5) then (6). Chemical restraint, hynotics, narcotics. Moderate doses only intensify excitement without producing sleep in acute delirium. Sixty to seventy grains of chloral were given on a few occasions. The risk, however, is very great, and besides does not affect the question of postural straps. This enumeration of alternatives refers only to the treatment of mania gravis and acute delirium, the only form of insanity characterised by continuous excitement and insomnia tending to fatal exhaustion. You say, Sirs, that I ought to have made myself aware of the uses of mechanical restraint. I knew all about the divergent views from Connolly down, but such views are beside my question. These men were discussing the 99,999 cases and I the other one—viz., typical acute delirium with cardiac dilatation occurring in a person aged fifty-six. I will sum up my view. If the patient will stay in bed and sleep, no restraint of any kind. The following statement by R. Percy Smith comes near, but not quite, to my case: "In patients who are wearing themselves out with rolling about or continuous movement some form of restraint, such as the dry and wet pack, is sometimes necessary." During the thirty-six days the patient was exercised once at mid-day in the airing court; and secondly at night in the corridor. On June 21st the temperature was normal, the wasting had ceased, the weight being 73 lbs. There was no dilatation or murmur as observed under chloroform, incoherence and inattention were still present, there was considerable strength, and six hours' sleep was obtained daily without hypnotics.

The Lunacy Commissioners discourage the use of mechanical restraint and seclusion. It is, therefore, necessary to keep the registers as clear as possible of entries of hours of both in all institutions under their inspection. The first may be avoided by "manual restraint," of which no entries need be made. The second, seclusion, by keeping the patient in a single room with unlocked door and an attendant outside, or a convalescing patient, to give notice of attempted egress.

Professional Discretion.—This is a matter of supreme importance to general practitioners. The Recorder of Birmingham has decided that I had no right to use mechanical restraint, it not being necessary for "medical purposes" under Section 40. Although I from the dock emphatically affirmed that in my discretion "rest" was a medical treatment, and was absolutely necessary to avert death, it mattered not. Although counsel cited Hack Tuke, Percy Smith, Deas, and Yellowlees—the latter of whom was said to be antiquated—it mattered not, the witness disagreed with all, and no more authorities were permitted to be cited. Now, if I have not any discretion, from whom must I get it, especially on an emergency. Must I ask the poor father of a child suffering from diphtheria for a stamped deed of indemnity against prosecution before I perform tracheotomy, lest some practitioner who only believes in intubation may witness against me, or the man who advocates antitoxin only, do likewise? Or must I demand the opinion of all the specialists around, requiring their fees in advance, lest some of them may appear against me in case I should be indicted? Or shall I proclaim myself an incompetent coward by abandoning the case? I know not. Medical witnesses in my experience act the part of prosecuting counsel. I hold the unique position, I believe, of having stood twice in the dock on professional grounds alone. The first time Mr. Justice Wills did not allow five hostile witnesses to impeach my discretion, saying that there was "an element of vindictiveness about which he could not speak calmly." He said practitioners were allowed almost unlimited discretion by all authorities on jurisprudence. This dictum would not have kept me out of prison last time, however.

Now in my fortieth year, I can truthfully assert that I have never shirked any case in surgery, midwifery, or gynæcology to which I was summoned. I fortified myself to meet each exigency. I never contravened the ethical code in the slightest degree. Then why this persecution? Shall my hair be turned white and the flesh worn off my bones by disturbed dreams of "docks" and visions of prison cells? Must I at forty abandon the profession in despair, with my youth gone, my spirits broken, and a financial wreck?

I am, Sirs, yours respectfully,

Oct. 21st, 1895. FITZWILLIAM R. A. EVANS.

[1] This figure appears to be as intended by the writer, though it is impossible to be certain from the copy, which in this respect is indecipherable.

"THE PHYSIOLOGY OF DEATH BY ELECTRIC SHOCK."

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Aug. 3rd there is an interesting letter on the above subject by Dr. W. S. Hedley containing extracts from an important paper by Dr. A. M. Bleile, Professor of Physiology in the Ohio State University. Dr. Hedley has done me the favour to send me this paper, to some parts of which, not quoted by him, I shall presently refer. Dr. Bleile states that when dogs were killed by a strong charge of electricity the condition of the heart and bloodvessels examined immediately after death was always the same. "The left side of the heart was quite relaxed, the right side was intensely gorged with blood, as were also the large veins in the immediate vicinity of the heart. ..... It was also noted that deep and extensive cuts made in the tissues were free from blood, that the arteries were quite small and contracted, and that the blood was crowded into the very large veins in the trunk." These, then, are the main anatomical facts, which are very interesting and significant, but I find it difficult to accept Dr. Bleile's explanation of the phenomena. He says: "Taking these facts, it was suggested that the current acted upon the arteries through the nervous centre which controls their diameter. It is well known that the arteries are supplied with a middle muscular coat in which the fibres are circular, and their contraction would of course cause a narrowing of the artery, rise of the blood pressure, and a consequent impediment of the heart's action; in fact, it has been experimentally demonstrated that the arteries can be constricted to such an extent as to produce a rise of blood pressure which the heart is unable to overcome, and the circulation will stop from this cause." The chief defect in this statement is that the writer makes no distinction between the large arteries whose middle coat is mainly composed of elastic tissue and the

Digitized by Google

terminal microscopic arterioles whose middle coat is entirely muscular. The elastic resiliency of the larger arteries helps the heart to drive the blood onwards, while the contraction of the muscular arterioles impedes the onward passage of the blood, and so causes distension of the large arteries and of the heart's cavities. The emptiness of the systemic arteries and of the left side of the heart, which is said to be constantly found after death from electric shock, is certainly not the result of contraction of the systemic arterioles, and no physiologist can suppose that electricity excites such contraction of the large arteries as to arrest the circulation. The great distension of the right side of the heart and of the large veins while the left cavities of the heart are relaxed and the systemic arteries are empty is the condition which is found immediately after death from what is commonly called asphyxia, but which should be designated apnœa.

When the blood pressure in the carotid is measured and the heart of an animal is exposed during the progress of apnœa it is constantly observed that in the first stage of the process there is an increase of systemic arterial pressure with great distension of the left cavities of the heart; in the final stage the pressure in the pulmonary artery rises while that in the carotid is falling, the right cavities of the heart and the venous trunks become distended while the left side of the heart and the systemic arteries are almost entirely bloodless.[1]

The explanation of the facts is that, in the first stage, venous blood passing into the systemic arteries excites contraction of the arterioles, with resulting distension of the large arteries and the left side of the heart. In the second stage of apnœa the blood, having become entirely deoxygenised, excites contraction of the pulmonary arterioles, the result being that the trunk and large branches of the pulmonary artery, the right cavities of the heart, and the large veins are gorged with blood while the left side of the heart and the systemic arteries are empty. The arrest of the circulation by the extreme contraction of the pulmonary arterioles obviously explains the engorgement behind and the depletion in front of the obstruction. If we assume that the electric shock arrests the breathing by paralysing the respiratory centre the appearances found immediately after death are completely explained, and I believe that these appearances admit of no other explanation. Dr. Shettle, in his letter in THE LANCET of Sept. 14th, says: "The absence of oxy-hæmoglobin in the blood after death by electric shock is a fact beyond dispute." It is also beyond dispute that this condition of the blood is invariably found after death by apnœa; and it is inconceivable that the absence of oxy-hæmoglobin could result from the direct action of electricity upon the blood. It has been suggested that the heart's action is suddenly arrested by the electric shock; but if this were so there would not be the great disproportion in the amount of blood on the two sides of the heart which is said to be constantly present. After death from a sudden arrest of the heart's action the amount of blood on the two sides of the heart is nearly equal; but in cases of death from apnœa the right cavities of the heart are found immediately after death to contain about eight times as much blood as the left, the proportion being, approximately, that of ounces to drachms. In an annotation in THE LANCET of July 27th (p. 223) reference is made to the post-mortem appearances in a New York criminal executed by electricity. It is stated that "two quarts of blood escaped when the skull was opened." The annotator truly remarks that there is not room in the skull for so much blood. The explanation is that in opening the skull, which must have been done before the chest was opened, a large sinus or vein was wounded, and the blood escaped from the veins of the neck and trunk, which were over-distended in consequence of the arrested circulation through the lungs. If death had resulted from cardiac paralysis such copious hæmorrhage from excessive intravenous pressure would not have occurred.

Dr. Bleile in his paper argues that arrest of the breathing is not the cause of death from electric shock, because in no case did resuscitation result from artificial respiration; but this is a fallacious argument. In the few cases in which artificial respiration was practised the electric discharge was excessive, from 96 to 525 volts, and applied for from 2 to 10 seconds. These strong currents probably inflicted irrecoverable damage upon the nervous centre. Then it is notorious that, when suspension of the breathing—as, for instance, from an overdose of chloroform—is known to be, in some cases, the cause of death, the most prompt and persevering performance of artificial respiration too often fails to restore natural breathing. The respiratory centre has been irremediably paralysed. Dr. Bleile found that when a dog was made to breathe nitrite of amyl a stronger current of electricity could be given without being fatal. From this the author infers that "death in electric shock is entirely due to the fact that the current produces a contraction of the arteries through an influence on the nervous system, and that this constriction of the arteries throws in such an impediment to the flow of blood as the heart is unable to overcome, and that when drugs are given to counteract this effect much larger doses of electricity than the ordinary can be borne." There is, of course, a partial truth in this statement, but it is incomplete and, I believe, in one important particular erroneous. It is assumed that electricity excites contraction of the arteries by its direct action upon them through the nervous system. On the contrary, I maintain that the facts are consistent only with the theory that the contraction of the pulmonary arterioles, by which the circulation is finally arrested, is a result of the apnœal condition caused by paralysis of the respiratory centre. I have in this communication described the successive phenomena of ordinary apnœa, and in the paper in THE LANCET before referred to I have shown that when the arterioles have been paralysed by nitrite of amyl, by atropine, or by an overdose of curara the phenomena are greatly modified. There is no increase of systemic arterial tension in the first stage of apnœa, no resistance caused by contracting pulmonary arterioles in the final stage, and consequently no resulting over-distension of the right cavities of the heart. In consequence of the absence of pulmonary obstruction the circulation continues longer, and the animal's life is considerably prolonged.

I have been told by two friends—one of them a physiologist—that they have recently read the report of a patient having been rendered unconscious by lightning and restored by artificial respiration, but neither of them could remember where the report had appeared. If any of your readers can refer me to the report of that or any similar cases I shall feel greatly obliged.

There is, I think, an interesting analogy between the arrest of breathing by an electric shock and the respiratory failure which Mr. Victor Horsley has proved to result from intracranial pressure, from a violent blow on the head, or from a bullet wound of the brain.[2] Dr. Kramer and Mr. Victor Horsley have shown by experiments on etherised dogs[3] that as a result of a bullet passing through the cerebral hemispheres there is first a slight fall of blood pressure, followed by a considerable rise of blood pressure. This rise of systemic blood pressure, as we have seen, always occurs during the first stage of apnœa. The authors have found that in some cases of this kind death may be prevented by artificial respiration. The full report of their experiments will shortly appear in the Philosophical Transactions.

Before I conclude this long letter I beg permission to indicate the manner in which the inhalation of nitrite of amyl, in all cases of suspended animation from the various forms of apnœa, serves as a most influential adjunct to artificial respiration.

In the paper before referred to[4] the following experiment is described: "Into the trachea of a small dog, prepared with the chest and pericardium opened and kept alive by artificial respiration, a glass T-tube was introduced, through which nitrous oxide gas was passed into the lungs, whilst the expired gases escaped into the air. As usual, first the left, then the right, cavities became distended, and in one minute the heart's action had nearly ceased from over-distension of the right side. Then, without loss of time, inhalation of nitrous oxide, *impregnated with the vapour of nitrite of amyl*, was substituted for the pure N_2O, by means of a two-way stop-cock, and the result was that almost immediately the distension of the right cavities began to subside, and in two minutes they had nearly regained their normal size." This experiment shows that even while atmospheric air was excluded from the lungs by nitrous oxide gas the over-distension of the right cavities was removed by the relaxing

Digitized by Google

effect of nitrite of amyl upon the pulmonary arterioles. This clear demonstration of the action of nitrite of amyl shows the value of that agent as an aid to artificial respiration in all cases of suspended animation from apnœa. Whatever the primary cause of the apnœa, whether hanging or drowning, the inhalation of an azotic gas such as nitrous oxide or nitrogen, a blow on the head or mechanical injury of the brain, the shock of lightning or electricity—in each and all of these cases the relaxation of the pulmonary arterioles by the vapour of amyl nitrite has a double effect, (1) it immediately lessens the weakening over-distension of the right cavities of the heart; (2) by allowing the blood to pass on to the left side of the heart and so to the coronary arteries, the contractile power of the heart's walls, which had been impaired by anæmia resulting from the arrested pulmonary circulation, is increased. I am, Sirs, yours faithfully,

Savile-row, Oct. 14th, 1895. GEORGE JOHNSON.

"THE BATTLE OF THE CLUBS."

To the Editors of THE LANCET.

SIRS,—After many days it seems that the seed which some of us have been persistently, if somewhat feebly, sowing is taking root, and here and there springing up. We have to show that we are not acting selfishly, but as much in the interest of the sick poor as our own. Provident arrangements made in accordance with the just demands of the profession tend to encourage independence in the working class and to obviate pauperism. Provident arrangements forced upon the profession by syndicates and insurance societies on their own terms, and chiefly in their own supposed interests, pauperise the working class and degrade the profession.

Eastbourne, Portsmouth, Lincoln, &c., have become centres of revolt against impositions which have become unbearable. It is necessary now that the movement should become national and cease to be merely local. I would suggest that in each town and district throughout the country medical unions should be formed, and that each union should regulate the provident question in its own district on the lines of the Eastbourne arrangement, modified according to the needs of each locality. Existing friendly societies and medical aid associations can easily make arrangements with the practitioners of their district, and those of their medical officers who have earned the respect and esteem of their clients will at once step into a position of comparative independence with a chance of private practice. All that these societies have to do is to accept the "wage limit," to consent to a reasonable provident payment, and the principle that each head of a household shall choose his own medical attendant without the presence of canvassing or touting.

To accomplish this all that is necessary is united action in the profession. I am, Sirs, yours faithfully,

Loughborough, Oct. 18th, 1895. J. B. PIKE.

To the Editors of THE LANCET.

SIRS,—As medical officer to a medical aid association I beg to take exception to the *ab uno disce omnes* strain of Mr. Lionel Stretton's letter published in THE LANCET of the 19th inst. That certain abuses do exist in the management of several medical aid associations and that these abuses are countenanced by the medical officers I admit; but I am unwilling to acknowledge that this is the rule, not the exception. In order to justify the existence of these institutions we must consider the causes which led to their formation. In the first instance, medical men confided the care of their club patients to the tender mercies of unqualified assistants; secondly, club notes were frequently given to malingerers in order to secure their votes; and, lastly, cases of gross imposition were often winked at. To procure the services of a medical attendant whose qualifications would be guaranteed friendly societies were obliged to coöperate, and in order to make their medical officers independent of individual members, as a precaution against fraud, it was found necessary to pay a fixed salary. To prove that this state of affairs did exist I should not have to go a thousand miles from home, but could instance several cases not far away where the wives of club patients have been attended by unqualified assistants, and at present there is practising in the district an individual whose only pretention to qualification is that he was assistant to a local practitioner the greater part of whose club practice he managed for some time. That imposition by certain friendly society members has been winked at can be easily proved, for within a very short space of time I have examined for a society either nine or ten members certified to be suffering from various complaints; in only one instance was there the least evidence of disease or infirmity, and my decision—that with this single exception they were able to work—was disputed by only one member, who was afterwards examined by an independent medical man and expelled from the society.

Now, Sirs, I do not wish to justify the action of those medical associations that treat their surgeons as mere money-making machines; but I do say that friendly societies have a right to provide themselves with the best medical attendance for the money they can afford to spend; and, furthermore, I would add that in my opinion the dignity of the profession is as safe in the keeping of medical aid surgeons as it is in the hands of those whose only right to dictate is that the practice they purchased has been reduced in value by the action of the clubs. I have been medical officer to an association for over three years, and I challenge any medical man in the district to prove me guilty of the slightest breach of medical etiquette. Before medical aid associations were brought under the notice of the General Medical Council I wrote to Dr. Leslie Phillips offering to resign my position if he thought by doing so I would benefit the profession. I am still prepared to act in the same manner under a like condition.

I am, Sirs, yours faithfully,

N. L. USHER SOMERS.

High-street, West Bromwich, Oct. 20th, 1895.

To the Editors of THE LANCET.

SIRS,—I have no wish to prolong this correspondence, but must again assert that our balance on the year's (1894) working was £40, and not £200 as stated by you. Our receipts for 1894 was £989 10*s.* 2*d.* and payments £949 1*s.* 1*d.*, leaving balance on year of £40 9*s.* 1*d.*, as per my previous letter. I am, Sirs, yours faithfully,

WM. COULSON, Secretary.

Lincoln Oddfellows' Medical Institute,
Lincoln, Oct. 22nd, 1895.

*** We refer Mr. Coulson to the balance-sheet of the institute for the year in question and our words.—ED. L.

"HOSPITAL ABUSE AT BRIGHTON."

To the Editors of THE LANCET.

SIRS,—In the interest of accuracy I beg your insertion of a quotation in my letter of Sept. 24th side by side with Dr. Waring's deduction therefrom in your issue of Oct. 12th:—

"A searching scrutiny ..... showed that 96 per cent. of the cases (out-patients) were entirely fit and proper subjects for gratuitous treatment, and though in the remaining 4 per cent. sufficient information could not be obtained, it was thought that even in these cases, were closer scrutiny possible, it might be shown that several could be received without any abuse of the charity."	"According to Dr. A. J. Richardson ..... 4 per cent. of the cases which were treated were not entitled to charity."

In my above-quoted extract from the hospital report it is evident that, when the "several" who could be received without abuse are subtracted from the 4 per cent., 4 cannot remain. Having been a member of the sub-committee which drew up this very clause, I may explain that this 4 per cent. was made up of three groups: (1) the unfit for charity; (2) the cases which it was impossible to duly investigate; and (3) the cases it was inadvisable to further investigate for various reasons. Now neither I nor the secretary of the hospital have given the proportions of these three groups. I am, Sirs, yours faithfully,

A. J. RICHARDSON.

St. John's-terrace, West Brighton, Oct. 14th, 1895.

"OVER-OPERATING IN GYNÆCOLOGY."

To the Editors of THE LANCET.

SIRS,—I shall be glad if you will kindly allow me space to state that I was careful not to fall into the error suggested by Mr. Tait in his letter of Oct. 12th, and that I did not refer to operations undertaken for the relief of uterine myoma. I am, Sirs, yours faithfully,

Southampton, Oct. 22nd, 1895. JOHN F. BULLAR.

*** This correspondence must now cease.—ED. L.

THE BATTLE OF THE CLUBS.

(FROM OUR SPECIAL COMMISSIONER.)

(*Continued from p. 945.*)

"SWEATING" OF MEDICAL MEN AT LINCOLN.

THE figures given with regard to the number of patients seen and the amount of medicine dispensed by the five medical officers of the two dispensaries which the friendly societies have established at Lincoln show that too much work is done to be uniformly well done. There must be hurrying over the work somewhere and sometimes, and therefore I have urged that reform was needed in the interests of the patients as much as, or perhaps more than, in the interests of the medical profession. Now I have before me what might almost be qualified as a manifesto emanating from the friendly societies themselves, and setting forth how much reform was needed when a better system than the present one prevailed. What, then, must be the state of affairs now? Formerly there were at Lincoln only club medical officers who worked under the usual conditions. These officers undertook to provide medicine and attendance for the members of the clubs at an annual payment of 3*s.* 6*d.* per member. The medical officers were able to attend to their private practice, and their connexion with the members of the clubs helped to increase it. Young practitioners, by the care they devoted to the club patients, could make a reputation which led to advantageous private practice. This was a direct incentive to devote themselves to their club patients. But, on the other hand, there was the fact that the pay was miserably low, and consequently the temptation to neglectfulness sometimes proved irresistible. The need of reform was then acknowledged, though the reform adopted has in reality made matters much worse. Strange to say, it is in seeking to defend the present system that these facts have been brought forward. In answer to the attacks against the friendly societies' dispensaries the *Lincolnshire Echo* published on April 5th last a letter setting forth, on behalf of the members of the friendly societies, the reason which led to the abolition of the old system. The arguments adduced for this purpose are worth quoting and noting. The author of the letter in question wrote: "The abuses and neglect which crept in brought such a great demand upon the sick funds, and dissatisfaction amongst the members, whose constitutions were sacrificed and lives endangered, that a remedy had to be sought out. On inquiry it was found that attendance on a club patient was a secondary consideration with the club doctor. 'Club patients' were commonly relegated to the care of assistants, usually inexperienced and often unqualified. Hours of weary waiting in passages, kitchens, and other unsuitable and uncomfortable places increased the complaint and frequently terminated by the kitchen-maid telling them to call again. The address and the treatment in many cases were harsh, and the attendance, especially if the doctor happened to be a Poor-law officer, the same as that given to a pauper and as a matter of charity; all were supplied with club physic and club pills. Needless to say, there were many honourable exceptions to this manner, and Lincoln boasts of having years ago a record of medical men devoted to the work."

The sufficient answer to this extravagant charge against the club system is contained in the last lines of the description itself, which admits that in Lincoln there was a record of medical men devoted to the work. Angels must not be expected under such an exacting system as the old club or the new medical aid association system. The wonder is that the patients were so well served.

The friendly societies of Lincoln, however, instead of combining so as to improve the position of their medical officers, organised dispensaries where they obtain a much greater amount of work for a much smaller amount of pay. Formerly the whole of the 3*s.* 6*d.* went to the medical officer, now the friendly societies "sweat" a big profit out of this contract price. Formerly the merchant tailor had his own workshop. If 3*s.* 6*d.* was the price allowed for the labour of making a waistcoat it all went to the workmen employed there. Now the merchant tailor saves himself the trouble of organising a workshop and gives the cloth &c. and the 3*s.* 6*d.* to a sweater, who takes the whole to his den in the East-end of London. There, by the subdivision of labour and by employing starving Polish Jew refugees from Russia, the sweater gets the waistcoat made for less than 3*s.* 6*d.* and thus "sweats" his profit out of the labour he employs. The only difference, as I have already remarked, between the East-end sweater and the dispensaries of the Lincoln friendly societies is that the latter make a larger percentage of profit out of the 3*s.* 6*d.* That such profit is made out of the labour of medical men is admitted in the following sentence which I quote from the above-mentioned letter written in defence of the action of the friendly societies: "All lodges are not connected with these dispensaries, and some employ private practitioners, but to the disadvantage of the members and the funds of the society."

There is another very important admission made in this letter which fully justifies the fears that the growth of the friendly societies will deprive the medical profession of their present means of existence. The writer says: "Over 250,000—a quarter of a million—of our countrymen have allied themselves with these medical institutions. The membership and funds of the societies have increased and are increasing immensely, and not until they are able to provide for members from 'the cradle to the grave' will the leaders, managers, and supporters of these associations consider their work completed. Men of all classes are now allying themselves with friendly societies, from the peer to the peasant; bishops, clergymen, ministers of all denominations, politicians, Members of Parliament, members of our county and city councils—all unite to help forward these societies, which are founded on principles of thrift, self-reliance, self-help, independence, benevolence, concord, friendship, love, and truth."

It is very remarkable that this defence of the friendly societies embodies accurately the very complaints the medical profession makes against these organisations. As fully explained when describing the position of affairs at Portsmouth, there was a great readiness to give medical aid to ill bread-winners for a small sum per annum; but then it was understood that, so long as the bread-winner was able to work, he should pay a proper fee for the attendance given to his family. Cases where the fees for attending families varied from £1 to £7 a year were described, though the head of the family, as a member of the Manchester Unity of the Oddfellows (the same society that has established one of the dispensaries at Lincoln), only paid 4*s.* a year for the medical attendance he himself received from identically the same medical man. I pointed out that, while the club practice in one instance only brought in about 4*d.* a consultation or visit, it was the means of securing many visits or consultations at a fee of 2*s.* 6*d.* But if, as proposed in the above letter, everyone is to be a member from "the cradle to the grave," it is no longer a question of merely insuring the bread-winner, but the whole family. Whence, then, will the 2*s.* 6*d.* fees come that are the compensation for the cheap club work done and the only material inducement to attend to club work carefully, attentively, without hurry, and without undue economy in the matter of the drugs dispensed?

All that I have said so far does not, however, represent the principal grievance on which the members of the profession at Lincoln especially insist. Their great complaint is that a large number of leading tradesmen and well-to-do men of independent means avail themselves of the friendly societies and obtain medical aid for 3*s.* 6*d.* per annum when they are well able to pay proper fees. In the face of this disgraceful fact the champion of the friendly societies is so blind to the points at issue that he deliberately boasts that "men of all classes" join the friendly societies. That is just the grievance. A gentleman who was formerly Mayor of Lincoln and is now alderman, is a leading member of the Oddfellows. Nor is he merely an honorary member, patronising the institution from benevolent motives; but he receives the medical benefits just as if he was a poor working man instead of a wealthy, successful tradesman and one of the most prominent citizens of the town. It has been calculated that last year, in exchange for the paltry club subscription amounting to only a few shillings, this gentleman and his family received medical attendance and medicine which, at the rate of 2*s.* 6*d.* per visit, would have amounted to £35. As, however, a person in his position might well be called upon to pay 5*s.* per visit, it may be said that through the connexion of this one family with a benefit society the medical profession has lost £70 in one year. Far from denying this gross abuse of an institution created to help poor

Digitized by Google

working men, the letter above mentioned actually confirms the fact by stating that "members of our county and city councils all unite to help and forward these societies." Further, it should be mentioned that when the General Medical Council held an inquiry into this matter the gentleman in question actually went up as a representative of the Lincoln Oddfellows. Another member of the Lincoln town council was a member of a benefit society, and his wife and children were attended by the club medical officer. He has now, however, recognised the false position he occupied and has sought the advice of a private practitioner, leaving his club officer to attend to the poorer members of his society. Among the various persons pointed out to me as being in receipt of medical aid from friendly societies were a master printer in a large way of business and several rich butchers. One of the latter has retired from business and lives in a handsome villa. Some master tailors, two of the principal tobacconists of the town, a person holding a high position in a foundry and earning a good income, the proprietor—or, at least, the manager—of a large hotel, a young man who is earning a good income in the beer trade, and even a dispensing druggist were all mentioned to me as being in receipt of medical aid, though they can well afford to pay proper fees. A practitioner who for many years had been in the service of one of the friendly societies dispensaries said that he was then obliged to see from eighty to ninety patients per day, and was convinced that at least 10 per cent. of these members of friendly societies could well afford to pay the usual fee for medical attendance, and had therefore no right to claim medical aid.

The presence of so many prosperous and wealthy tradesmen and others on the books of friendly societies, not merely as patrons or as participants in financial benefits, but as claimants of medical aid, is not only a great injury and injustice to the medical profession, but it is also very detrimental to the interests of *bonâ-fide* working men and to others who are morally or rightfully entitled to medical aid by reason of their slight resources. The well-to-do members of the friendly societies, being better educated, more skilful administrators, and better writers and speakers, have naturally been elected on the managing committees of these organisations. It has been urged that not only does the system tend to make medical men neglect the great crowd of patients that come upon them, but that it also tends to make the medical officers give far more attention to some of the patients than to others. Surely, as the payment is the same the treatment should be the same, but this is said not to be the case. What, then, has become of the brotherhood of which these societies boast? The medical officers of these dispensaries have to spend an undue amount of time in visiting members of the committee and their middle-class friends. They have, consequently, less time to give to the more numerous but poorer members of the society. It is a beautiful picture for the British workman to contemplate. This sworn adversary of the sweating system, this friend of fair play and a fair day's wage for a fair day's work, has elected to manage the friendly societies organised for his benefit a number of shopkeepers, small capitalists, and other middle-class men, who only pay the same subscription as the workmen. It was even proposed that one of the medical men should stop in apart from the ordinary consulting hours so as to receive the better-class members, though it was never proposed that for this extra accommodation and privilege the annual subscription should be augmented. There are to be first-class patients, but all are to pay third-class fares. It was on this point that one of the medical officers employed at Lincoln resigned. He had to attend morning and evening at the dispensary to give medical advice to the members of the society, and the waiting-room was then crowded with working men and poor people. The wealthier members did not like to come there and mix with a rough crowd, therefore they proposed that the medical officer should stop in during the afternoon so as to receive them. The medical officer, however, refused to sacrifice his afternoons so as to see some half-dozen well-to-do members who, in spite of their wealth, did not pay higher subscriptions than the workmen. Ultimately this medical officer had to resign because he did not sympathise with and help the wealthy members of the society who were anxious to receive medical aid for the 3*s.* 6*d.* per annum workmen pay, but would not put up with the rough accommodation and surroundings workmen have to endure. With the dispensers the grievance is the same as with the medical officers. The wealthy members do not like to wait in the crowd for their medicines, so they want the dispenser to stay after hours and give them their medicines separately and in a more select company. Such is the brotherhood of these dispensaries. The middle-class committee-men have introduced, for their own benefit, a system of privilege which is to the advantage of their own class, but is paid for out of the funds which, in the main, are provided by the working class. If someone gets more than his share someone else has to suffer. In this case it is the poorer members of the societies who pay for the richer members. A well-to-do tradesmen, the owner of house property, pays 3*s.* 6*d.* a year and 8*s.* for all his family. When he is ill the medical officer hastens to his house, a servant opens the door, keeps him waiting, and a good quarter of an hour is devoted to this one case. As a natural consequence, the workman hard by, who pays exactly the same sum, is treated with much greater haste. Being a workman, and feeling that he is not paying much for his medical attendance, he does not keep the medical officer waiting and is grateful for what attention is bestowed on him. He would not, however, be so contented if he realised that the visit was brief and hurried because too much time had been devoted to the wealthy brother member who lives in a luxurious villa.

Fortunately, there are at least a few working men in Lincoln who are beginning to realise how serious a grievance this inequality of treatment has become. Unfortunately they are, for the most part, but poor speakers, and though they feel very sore on the point they have not yet plucked up the courage to attack the managing committees. The rank and file of the friendly societies are sadly in want of leaders and speakers. If such leaders were forthcoming the privileges which middle-class families enjoy as members of friendly societies and at the expense of their poorer fellow-members would soon be swept away. The working-class element would also, I am convinced, indignantly abolish the sweating system. It cannot be repeated too often that medical aid is only justified within a certain wage limit, and that if wealthy members are admitted abuses will arise that are not only detrimental to the interests of the medical profession, but are equally injurious to the well-being of the working men themselves.

If the working men will not take action it is difficult to say what, for the moment, can be done to prevent this state of things. It is no use attempting to persuade the five medical officers of the two dispensaries to resign till there is such organisation or unanimity of feeling among the profession throughout Great Britain as to prevent other practitioners taking their positions. Public and professional opinion has to be further stirred and moved on this question. In the meanwhile perhaps a list might be published of wealthy persons who avail themselves of the medical aid organised only for the poor; and certainly an appeal should at once be made to honorary members of the societies who have lent their names so as to strengthen what they imagined were merely benevolent institutions. The Bishop of Lincoln is, I am told, an honorary member of one of these bodies, and yet it is very certain the reverend Bishop does not mean by this to signify that he approves of the sweating system. Pressure from above and pressure from below could be brought to bear upon the managing committees till they are compelled to establish a wage limit. If this is not done then the medical profession will have to discover some means of preventing qualified practitioners from accepting office in dispensaries where the sweating system is enforced and no wage limit is established.

Lincoln, October.

SOME OF THE HOSPITALS IN NORTHERN ITALY.

(BY A HOLIDAY CORRESPONDENT.)

Ospedale Maggiore in Milan.

DR. GRANDI, the medical director of the Milan Hospital, kindly gave me his last report, which consists of 285 pages, being chiefly statistics very carefully worked out. It is dated 1894 and refers to the three years ending in 1891. The Italian custom seems to be to publish statistics only every three

Digitized by Google

or five years, and then somewhat tardily. The annual admissions on the average of these three years are 22.735, with 2828 deaths. The daily admissions vary from 15 on Christmas Day to 120 in August, and the deaths from 1 to 20 per day, while the average number of in-patients ranges from 1852 to 2456. In one year as many as 1087 cases of small-pox were treated, of which 63 broke out in the hospital. The average diphtheria patients number 296 in the year, including 17 which arise in the wards, and the death-rate is 47 per cent. Typhus fever would seem to be rare, for only 5 cases are admitted annually. There were only 17 cases of measles, 15 of scarlet fever, and 21 of whooping-cough. There is a special report on Dr. Visconti's work with Koch's tuberculin, which is now no longer employed. The summing-up briefly is that it is useless as a cure for tubercle, but of value for diagnosis, especially in the case of animals. Dr. Visconti spoke to me very highly of Koch's work, and believes that to him is due the credit of initiating the system of serum injections, of which that for diphtheria is a natural sequence. The great prevalence of enteric fever in Milan calls forth a very interesting report. There are 559 cases a year treated in one military and three civil hospitals, with a death-rate of 12·6 per cent. Besides this there are 147 deaths from enteric fever in the town, and if it is supposed that the mortality in the town is the same as that in hospital about 1176 cases must be added to the hospital ones, and this figure will, perhaps, include mild cases not diagnosed. This gives an annual total of 1735 patients with 218 deaths certified from one preventable disease alone in a town of 315,000 people. On investigation it appears that half the patients suffering from enteric fever come from seven of the forty-one parishes of the town, and, further, that these seven districts are intersected or surrounded by old canals—now open drains. No less than 1069 "delirious" patients are admitted to the Ospedale Maggiore in the year, besides 315 lunatics. The number suffering from scabies is 646. During the three years in question there have been 49 ovariotomies, with 8 deaths. The annual admissions include 150 "drunk" and 67 patients who attempted suicide, mostly men between twenty and forty years of age; also 15 cases of hydrophobia were treated during the three years. Since 1889 there has been an anti-rabies institute at the hospital, 97 cases having been treated in 1890 and 157 cases in 1891. The pathological laboratory was opened in 1868 by Dr. Visconti and has been under his superintendence since. The chief causes of death found in the large post-mortem room, which is furnished with five tables, are in the following order: tubercle of lungs, senile decay, pneumonia, broncho-pneumonia, diphtheria (occurring all through the year and chiefly in children under ten), and, lastly, cerebral hæmorrhage. But in a year only about 610 necropsies are accurately made. Besides ordinary notes a register is kept giving a *résumé* of the post-mortem examinations, and also a reference by numbers to other books where very thorough details are written of the clinical notes, microscopical results, and museum preparations. When a patient dies in the wards he is kept in his bed for three hours, and then for a further period of six hours on one of ten beds in the deadhouse. Each of these beds has at its head an electric bell rope, and the porter told me that he had been called up by this bell six times in the last six years, each time occasioned by some increase of rigidity in the corpse. Dr. Visconti and his assistants also examine under the microscope all clinical material sent to them from the wards, and of this work accurate registers are also kept. I was thus able to see at a glance how many times the eggs of various entozoa had recently been discovered in the fæces of in-patients. There are some out-door charities in connexion with this hospital, the most important of which provides for the care of 32,000 patients a year at their own homes, the average visiting list numbering 246 per day. No modern hospital report is complete without a reference to influenza, and here there is a list of 38 epidemics which have occurred in Italy, going back to December, 1173, and March, 1259.

Mombello Lunatic Asylum.

This is the chief madhouse for Milan province and is distant one hour's journey by train from that town. It merits a short description because it is the best hospital which I met with in the north of Italy. It has been ably superintended for the last thirty-two years by Dr. Gonzalez, who most kindly devoted a whole afternoon to showing me round. He told me he was an ardent disciple of Conolly and glories in having almost abolished restraint. His method, which is suited to his own generous enthusiasm, is to treat all his patients like children, patting their cheeks and listening for a moment to each of them. Needless to say he knows every one and they all brighten up at his approach. However, I saw another side to his character when he thundered at an old monomaniac who had just written him a threatening letter. On the whole, asylum physicians seem to require very little protection, and indeed get very little from the untrained attendants during their rounds. It must be remembered there is no Broadmoor in Italy, and every county asylum contains a dangerous homicide or two. The hospital consists chiefly of nine pavilions for patients, besides all necessary offices, connected by a narrow-gauge line for trucks. There are 1422 patients, and the attendants are reckoned at the rate of 1 in 10 for ordinary cases and 1 in 3 for the excited ones, religious sisters being strongly disapproved of by Dr. Gonzalez. He has six assistants lodged in the central building, once a palace and inhabited by Napoleon I. It stands on a commanding hill and is surrounded by forty acres of land, partly tilled by the patients, some of whom I also saw weaving, tailoring, plaiting, and making maccaroni. The mattresses of the beds were stuffed with seaweed (zostera marina) from Genoa, which, besides being very cheap, is antiseptic and does not harbour insects, and also cannot burn when lighted by an ordinary match. Among the patients in the gardens and the workrooms and playrooms I saw several general paralytics and many pellagra insane, both men and women, and in one airing court I was suddenly addressed in English by a Maltese who had a chronic alcoholic history. About 1 patient in every 70 had more or less goitre, and there was a well-marked hermaphrodite aged fifteen years in the female wards suffering from melancholia. There were also among the show cases 3 microcephali, 2 of them being brother and sister. They knew each other when brought into the same room, and kissed sadly and noisily.

Lunatic Asylum at Voghera.

An hour's railway ride from Milan in another direction there is the asylum for the province of Pavia, under the superintendence of Professor Raggi of the University of Pavia, who good-naturedly placed himself at my disposal. He has two resident assistants, and the attendants are calculated at the rate of 1 to 10 patients. The average number of patients is 470 and the annual death-rate is 66. In going through the wards I noticed that many were tied in bed with a stout band or in camisoles, and in the infirmary ward I counted sixteen men so tied, including several general paralytics. However, this is chiefly for the convenience of the attendants, and a daily list is kept of the restrained epileptic and the workers. For instance, on the day previous to my visit 5 men and 5 women were reported as "clamorous," 16 men and 7 women were under restraint, 4 had epileptic fits, 11 had been violent or had received bruises, and 2 women were menstruating; 70 men and 105 women were on the workers' list, while 200 men and 111 women were from various causes declared to be unable to work. Professor Raggi showed me an interesting collection of skulls and of brains preserved by the Jaccomino method. I learnt at this asylum and others that there are no visiting lunacy commissioners, and also that there is no general lunacy law for Italy, though Crispi has tried to introduce one. Every province has its own local regulations, and in most of them one medical man's certificate is enough to insure admission into an asylum. Much good work is being done by the medical men of North Italy, but they have not yet been carried very far on the modern waves of asepticism, hygiene, and scientific nursing. It is this latter which prevents the notions of restraint in asylums from being quite up to English date.

BIRMINGHAM.

(FROM OUR OWN CORRESPONDENT.)

The Privileges of Benefit Societies.

IT is well for the working man to bear in mind that in insuring his life in a benefit society he is bound by the rules of the society, and that there are liabilities as well as benefits entailed by his membership. These facts were strikingly illustrated in a case recently tried at the county court. A man sued the secretary and trustees of Court Friar Tuck of the Ancient Order of Foresters for £3 5*s.* which he claimed as arrears of sick pay; the answer to this claim

Digitized by Google

was that the plaintiff had forfeited the amount under the rules of the Order. According to the rules any such question in the first instance had to be referred to arbitration, with an appeal from the lodge to the district, and so on until a final court of arbitration was reached. Instead of this the plaintiff had gone direct to the county court. The judge there informed him that at this stage there was no jurisdiction to help him. He might come back to the court, but people who joined voluntary societies must abide by the rules. The law is ready to provide a remedy in cases of unfair advantage or ignorance, but it is well that a reminder of this kind should be thoroughly known by those who join for prospective but mutual benefits.

Queen's College.

Since the removal of the medical faculty from this college things have gone on in a bad way. At the annual meeting summoned a few days since only four out of thirty-two governors put in an appearance. There was consequently no quorum. The same thing happened at the previous annual meeting. It seems that the college has now only nine students, and that during the last year there were but three entries. The saying of a deceased physician appears to be likely to be realised when he observed some years ago that "the grave of Queen's College was dug, and he, the grave-digger, stood at its side." Certainly theology left to itself does not flourish unassisted by the departments which were transferred to Mason College.

Insanitary Dwellings.

In one instance lately brought under the notice of the authorities the skeletons of two children were found in a cellar of a house. The owner carried on the business of an undertaker. The excuse offered was that the bodies had been received for burial, but the amount paid in such cases was so small that he only made a journey to the cemetery when he had a number to bury. The two bodies discovered were brought in a year ago, and although he had the certificates of death he did not cause the remains to be interred. Evidently any stick will do to beat a dog with, but an excuse of this kind ought not to be taken for the violation of a duty not only to the parents of the children but to the community at large. For another instance a man was summoned for having in his occupation a railway carriage in such a state as to be a nuisance or injurious to health, and so overcrowded as to be injurious to the health of the inmates. The carriage was divided into three compartments, with a total length of 20 feet and an extreme breadth of 7 feet. Exclusive of furniture about 280 cubic feet were allowed for each of the two occupants. An order was made for its removal. It is true that many people live in worse conditions than thus represented, but this does not alter the facts as pronounced by sanitary laws.

Midland Medical Society.

The inaugural meeting for the present session is to be held on Nov. 7th, when Dr. W. S. Playfair will give an address on the Nervous System in connexion with Diseases of Women. From the well-known work which Dr. Playfair has done in this direction, and the popularity of the society, a large meeting is expected.

Oct. 22nd.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

Port Sanitary Authority for Manchester.

THIS important question has advanced a step further. A conference of riparian authorities along the banks of the Ship Canal was held a week ago in the Lord Mayor's parlour. It was convened by an order of the Local Government Board, which was represented by Dr. Barry, one of the inspectors. He explained that under the Public Health Act of 1875 every sanitary authority bordering upon a waterway had certain duties imposed upon it with regard to the passing of ships and the health of the people on those ships, which, for the time being, were regarded as houses. There were also the Cholera Orders of the Local Government Board to be observed by these riparian authorities, acting in concert with the Revenue or Customs House authorities, and thus forming the first defence against the introduction of cholera into this country. He pointed out that where there were numerous authorities it was an advantage that there should be one responsible for carrying on the work. In the Manchester port there were sixteen or seventeen authorities, some on the Canal and some on the Mersey, and it was at present the only one in the country without a port sanitary authority. As to the "plant," as he termed it, a medical officer of health and one or more inspectors of nuisances would be required; also hospital accommodation and a mooring station where ships could be disinfected. Dr. Barry suggested that an arrangement might be made with the Liverpool authorities, who had an admirable station of the kind in the Sloyne. It would be difficult to find one altogether suitable in the Canal. Mr. C. H. Beloe, deputy chairman of the port sanitary authority of Liverpool, said it was vitally important that an infected vessel should not enter the tideless waters of the Canal; so that Manchester would have to do the work of inspection at the Customs station in the Mersey, and the Liverpool authorities might possibly object to two jurisdictions in the tideway. It had suggested itself to him that the authority of the port of Liverpool should undertake the work of examination with regard to infectious diseases, leaving to Manchester the ordinary sanitary inspection on the arrival of vessels in the Canal. The only question would be what proportion of the cost of the Liverpool work the Manchester authority should bear. Alderman Walton Smith, chairman of the Sanitary Committee, and Alderman Mark spoke of the offer Mr. Beloe had made on behalf of Liverpool as being most generous. A motion to the effect that a Manchester port sanitary authority should be formed was carried *nem. con.*, and also one that representation should be in proportion to contribution.

Waste Products in the Streets.

Numerous "orderly boys" are to be seen in the streets sweeping up horse droppings and other rubbish all the day. This certainly is to be commended. At the last meeting of the council, however, it was moved that the Cleansing Committee should report on the advisability or otherwise of providing on the footpaths suitable receptacles in which pedestrians—as the resolution somewhat pedantically has it—may deposit waste paper and other waste materials. It was said, on behalf of the committee, that some time ago receptacles were provided for the purpose, but "people mistook them for post-office pillar-boxes and put their letters in them." It is not surprising, therefore, that the resolution was lost.

Grant to the Manchester Museum.

The discussion on this subject was resumed at the council meeting last week, and, after a series of speeches nearly as long and impassioned as those which preceded the loan of several millions to the Ship Canal, it was decided, happily for the credit of the corporation, to grant the sum of £400 a year to the museum, as recommended by the Free Libraries Committee. This committee spent last year £19,703, while the amount that would be raised by the rate to which it is entitled would be £24,186 a year; the grant, therefore, will not cripple the libraries. As the benefits of this free museum, said by Sir W. H. Flower to be in some respects one of the best in the country out of London, extend over a wide area, it may be hoped that the county councils of Lancashire and Cheshire will give some help.

Extension of the Infirmary.

The resolutions of the grand committee, reported last week, do not mark any great advance. Instead of deciding on a definite course all the ground is again to be traversed. No doubt it is a serious matter to determine on rebuilding at a cost of £200,000; but there is reason to hope that the money will not be a serious difficulty. It would, however, give an opportunity for clearing away from the foundations all the old soil saturated with sewage, and all the remains of the porous brick drains of former days, and of starting afresh rid of this ancient filth. The plans for the wards, their adjuncts, and the administrative quarters could be arranged in the best possible manner, untrammelled by the defects of the present building. The alternative schemes for patching up or putting on another storey—almost unanimously condemned by the medical staff—would perpetuate many evil things, such as long dark corridors communicating with each other all over the building and preventing the possibility of isolation, and would do away with all chance of a clean foundation. Much has been done, at great cost, to improve the sanitary arrangements and condition of the present building, but the defects of construction are radical. If these schemes

Digitized by Google

are adopted for the sake of cheapness the result will ever remain a diappointment and a failure, and the principal hospital of Manchester will be a monument showing how far she has lagged behind the knowledge of the time and how she has allowed the provision for the sick and for clinical work to stand contrasted in their poverty with the splendid appliances for teaching at the Owens College.

Oct. 22nd.

NORTHERN COUNTIES NOTES.

(FROM OUR OWN CORRESPONDENT.)

Villa Garden Settlements.

THE Northern Allotments Society has purchased an estate of 215 acres at Stocksfield to be converted into a villa garden settlement. This is the third estate the society has purchased and laid out in the near neighbourhood of Newcastle within the last few years, so that it may be concluded the former ventures have been successful. The Stocksfield Estate has been divided between sixty-six owners. The object of the society is to induce dwellers in Newcastle and the district to build and to occupy houses on portions of land of not less than one acre in extent. This is an excellent movement, and one which, as the crowded business centres of our large towns cease to become residential, is likely to be imitated wherever facilities for villa garden settlements exist.

Is Crime Decreasing?

Mr. J. T. Wharton, the able and experienced chairman of the Durham Quarter Sessions, thinks that it is, as the number of persons now brought before him is considerably less than it was some years ago. The *Newcastle Daily Chronicle*, however, demurs to the conclusion, and points out that a smaller number of prisoners does not necessarily prove that there is less crime. In support of this contention the amount of undetected crime in the country generally, and in the North particularly, is cited. It appears that in the immediate neighbourhood of Newcastle during the last few years at least five undoubted murders have been committed and no one has been made responsible. We hoped that education would diminish crime. Can it be possible that criminals are now sharper than they were in avoiding detection, or is there something wrong with our means of detecting crime?

High Death-rate in the North of England.

For the last few months the death-rate in the usually healthy borough of Sunderland has been abnormally high, owing chiefly to an outbreak of typhoid fever, as to the cause of which a Government inquiry is being held. It is not in Sunderland only, however, that a high death-rate prevails just now. In the district governed by the Morpeth rural council, the greater part of which is agricultural and pastoral, a mortality of 31 per 1000 is officially reported. This high death-rate is not due to zymotic disease, and the mortality is chiefly among children under five years of age, the causes of death being returned as diarrhœa, debility, and wasting. In the colliery villages of Ashington and Hirst the rate of infantile mortality is particularly high, being at the rate of 30·6 in the former and 54 per 1000 in the latter place.

The Tyne Piers.

After upwards of thirty years' continuous work these magnificent piers at the entrance of the river are finished. Lord Salisbury, the Duke of Devonshire, Mr. A. Balfour, and Mr. Goschen have all been asked to declare them open on Nov. 6th, but unfortunately none of these distinguished statesmen is able to accede to the commissioners' request, and consequently it has been determined to postpone the function till May, 1896. It has been suggested that the Prince of Wales might then be willing to perform the ceremony.

Wear Valley Extension Railway.

A long-talked-of project has just been completed. This line, some nine miles in length, made by the North Eastern Railway Company, from Stanhope to Wearhead, has this week been opened for traffic. It runs through a very beautiful district, hitherto not easily accessible, and in addition to opening up an isolated neighbourhood it is hoped that it may be the means of doing something to revive the now almost extinct industry of lead mining in Weardale, and thus preserve from extinction a stalwart and estimable class of men—the Weardale lead miners.

River Tyne Port Sanitary Authority—Resignation of Dr. H. E. Armstrong.

Dr. H. E. Armstrong has resigned his appointment in connexion with the above-named authority, and his resignation has been accepted. Dr. H. E. Armstrong has acted as medical officer to the Tyne sanitary authority for fifteen years, and resigns in consequence of a desire having been expressed by the town council of South Shields that the medical officer should reside at the mouth of the river, and not in Newcastle.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Opening of the Winter Session at the Edinburgh University.

THE winter session of the Medical School of Edinburgh began last week. In the University several of the professors delivered introductory lectures on subjects of current interest. Sir Thomas Grainger Stewart, in the class of practice of medicine, discussed the Nauheim treatment of heart disease and the treatment of tetanus and diphtheria by means of antitoxines. He traced the discovery of these and quoted statistics showing the value of the treatment in diphtheria. He also referred to some of the unpleasant symptoms which sometimes followed the use of antitoxin. He likewise alluded to the difficulty of preparing the antitoxin, and thought that failure might in some instances be due to the inferiority of the antitoxin employed. He spoke of the certainty that other antitoxins would be discovered, and paid a warm and suitable tribute to those who had done so much to develop this side of science. In the class of midwifery Professor Simpson reviewed the history of the chair since its inauguration in 1726. He believed it to be the earliest instituted chair of midwifery in any university. At the close of his lecture he referred to the death of Dr. Thomas Keith, who was one of the most illustrious of the men Sir. J. Y. Simpson trained. Dr. Keith and Dr. Mathews Duncan were assistants to Sir James Simpson at the same time, and they both took their share in the experiments that resulted in the discovery of the anæsthetic properties of chloroform. After graduating Keith was house surgeon to Professor Syme, who recognised his rare surgical gifts. He joined his brother, Dr. George Skene Keith, in practice, and was largely engaged in general practice before he devoted himself to the class of operations which had given him a world-wide fame. It was curious to note the influence of the two masters on the career of a pupil in whom they both took pride. Syme trained his surgical instincts, and Simpson gave them direction. Syme and the surgeons of Edinburgh generally condemned the operation of ovariotomy and denounced the operators; Simpson and the obstetricians generally maintained its justifiabilility and encouraged the younger men to operate. There were long and keen debates on the subject in the Medico-Chirurgical Society, and it was owing to the success of Keith's first six cases, which were laid before the society in 1863, that the opposition was silenced. In pathology Professor Greenfield, and in surgery Professor Chiene, dwelt upon Pasteur and his work; Professor Chiene also referred to Dr. Thomas Keith's work in surgery.

Professor Annandale's Health.

I am glad to be able to state that Professor Annandale has made so much progress towards recovery that he has been able to meet his clinical surgery class.

Scarlet Fever in Edinburgh.

Scarlet fever is endemic in Edinburgh, as it probably is in all large centres of population. In Edinburgh, owing to compulsory notification, the majority of the cases are known. From time to time the disease becomes more widely epidemic; in fact, as soon as a fresh supply of susceptible children pass from infancy this takes place. Occurring at this season of the year, it necessarily interferes grievously with school attendance, and children attending school are doubtless more liable to meet infection than if they were carefully kept at home. But if it comes to be a question between attending school and playing about the streets and closes I doubt if the former is as bad as the latter. Some nervous people think that an epidemic of scarlet fever would cease if Board schools were closed, but I fear that no such simple remedy would suffice. Every year almost there is

Digitized by Google

more or less of an epidemic extension of the disease, and not much is heard of it until it invades the better quarters of the town, but when it does people write to the newspapers and express surprise that sanitary officials cannot prevent this and make suggestions as to how it might be avoided. All this may have its good side, but until the parasite of the disease is discovered we are not likely to see scarlet fever successfully held in check. In Edinburgh at the present time there has been the usual outcry, and the extent to which the city hospital is being used has given people the idea that the epidemic is exceptionally bad, and they cry out for additional measures for repression. The extreme infectiousness of the disease, the difficulty in securing sufficient isolation, the indifference of the great bulk of the lower classes to the risk of infection, and the fact that many mild cases are allowed to associate freely with other children make the stamping out of scarlet fever, or even the restraining of its extension, practically impossible with our present knowledge.

Death of Dr. Messer.

Dr. John Cockburn Messer, Deputy-Inspector-General of Hospitals and Fleets, Royal Navy, died last week in Edinburgh. He was a graduate of Edinburgh of 1851 and a Fellow of the Royal College of Surgeons of Edinburgh, and had seen a good deal of service.

Lectures to Sanitary Inspectors.

Dr. T. Pearson Munro, lecturer on public health in Anderson's College, Glasgow, is to give during the winter a series of lectures and demonstrations to the sanitary inspectors of the city on Chemistry in its application to Sanitary Work.

Medico-Chirurgical Society, Glasgow.

At a meeting of this society on the 18th inst. Dr. Geo. S. Middleton gave a clinical demonstration on a series of nervous cases. The following cases were included in the demonstration: (1) a child with spastic diplegia and athetoid movements; (2) a young woman with post-hemiplegic athetosis; (3) a man, the subject of acquired syphilis, with bilateral facial paralysis and absolute deafness; (4) a case of old-standing facial paralysis, with contracture and secondary over-action; (5) a woman with bulbar paralysis, muscular atrophy, and increase of reflexes; (6) a boy with peripheral neuritis due to administration of liquor arsenicalis; and (7) a man who had recovered from severe peripheral neuritis, but in whom the knee-jerk was still absent.

Oct. 22nd.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

St. Vincent's Hospital, Dublin.

THE address at the opening of the medical session at St. Vincent's Hospital was delivered by Mr. R. F. Tobin, F.R.C.S. Irel., surgeon to the hospital, who took for his subject Some Questions of Medical Education, urging upon his hearers the supreme necessity of acquiring the faculty of observation in the hospital wards, and assuring them that without cultivated powers of observation no mere book knowledge can be turned to use in the practice of their profession. The first two years of the five years' curriculum are almost altogether occupied in the Dublin school with the study of sciences that form the foundations of medicine — viz., anatomy, physiology, physics, and chemistry. During the third year, however, students can give a great deal of attention, and during the fourth and fifth years almost their whole attention, to medicine and surgery proper. There are thus two stages in the curriculum—a preliminary scientific stage and one devoted directly to medical problems. Students, however, do not spend their time during this second stage to the best advantage, for in place of applying themselves wholly to hospital practice they are obliged to attend the schools for theoretic lectures in medicine and surgery and for examinations in connexion with these lectures, and these so dominate their views that even in the hospital wards many of them are on the look-out for answers to examination questions rather than interested in watching the changes in the patients. The student is reluctant to make records of cases, for he knows that, from an examination point of view, it does not pay, and if towards the conclusion of his course he is offered the position of resident pupil in a large and busy hospital he often refuses it, because he is going in for his "Final," which it is essential to pass. Medical education, therefore, notwithstanding a large amount of hospital attendance, is literary rather than practical, and this system has the serious defect of neglecting the faculty of observation. This undesirable state of affairs has been brought about by the circumstance that the regulations require the theory of medicine and surgery to be condensed each into a course of fifty lectures, and at the same time refuse to recognise systematic theoretic lectures given in hospitals in conjunction with practical work. The obvious remedy is that regulations shall be issued applying to the teaching of medicine and surgery the same principle that has been applied to the teaching of all other arts and sciences—the principle, namely, of making theoretic and practical work go hand in hand. Knowledge obtained by the observation of cases is deep, abiding, and useful, in comparison with that which is reached altogether through words.

If it is right for a student to receive his medical and surgical training at a hospital, it follows that his hospital teachers should have a voice in his qualifying examinations, assessors from the Licensing Body whose qualification is sought, of course, attending such examinations. These changes in the method of conducting medical education would not be difficult to carry out, and their effect would be far-reaching. The objections urged against them are chiefly two, the first being that the clinical teaching in hospitals is not sufficiently full and systematic to warrant the abolition of theoretic lectures in the schools. But these lectures, though only fifty in number for medicine and for surgery, are supposed to complete the education of the student in these most extensive subjects, and so hospital teachers, relieved from the responsibility of giving systematic instruction, tend to "walk the wards" with their pupils in a rambling and drifting fashion. The second objection is that hospitals do not possess museums, such as are attached to some of the schools, the specimens of which are useful in illustrating lectures. The answer to this is that in hospitals there are specimens of both life and death, of men and parts in which disease is active, and of men and parts in which it has done its work. Another superiority of hospital teaching over museum teaching in this branch of study is that in the former the natural average proportion of the various classes of disease is maintained; but in the latter there is no such proportion, for museums abound in curiosities and despise common things. Museums are of use for the purpose of making additions to existing knowledge, but not for the laying of its foundations.

The Rotunda Hospital, Dublin.

On Wednesday afternoon, Nov. 27th, the new wing of the Rotunda Hospital will be opened by her Excellency the Countess Cadogan in the presence of a large and representative assembly of the citizens of Dublin. On the previous evening, the 26th, a conversazione and Cinderella dance will be held in aid of the complete equipment of the new wards and building.

The Fatality at Jervis-street Hospital.

A man named McNamara, who was accused some months ago of negligence in causing the death of a gentleman who stepped into the shaft of the lift at the Hôtel Métropole, Sackville-street, recently attempted to commit suicide, and was accordingly confined in Jervis-street Hospital under the charge of two members of the police force. He managed, however, to elude their vigilance, and jumping through a window fell some forty feet, sustaining injuries which proved fatal in a few hours. The case of Mr. McMarr, the gentleman who was killed at the Hôtel Métropole, was somewhat remarkable from the surgical point of view. It was proved at the inquest that he had fallen a distance of only eight feet and a half, and that he was found standing at the base of the shaft. The injuries which he received were notwithstanding of a most severe character, including rupture of the diaphragm and rupture with displacement upwards of the stomach.

Irish University Education.

Irish University education will probably soon again be thrown into the political melting pot, but in what form it will emerge it is difficult to say. The present state of affairs is not satisfactory to anyone, and quite recently the whole question has been reopened

Digitized by Google

by a series of resolutions passed by the Catholic archbishops and bishops. After stating their grievances they say their claims would be satisfied substantially: (*a*) by the establishment and endowment in an exclusively Catholic or in a common university of one or more colleges conducted on purely Catholic principles, and at the same time fully participating in all the privileges and emoluments enjoyed by other colleges of whatsoever denomination or character; (*b*) by admitting the students of such Catholic colleges, equally with the students of non-Catholic colleges, to university honours, prizes, and other advantages; and (*c*) by securing to Catholics, in the senate or other supreme university council of a common university, should such be established, an adequate number of representatives enjoying the confidence of the Catholic body. The question of how fairly to settle the claims of all parties in Irish university education is a very difficult and thorny one. Three courses suggest themselves:—1. A great central Irish university might be established embracing Trinity College, the Queen's Colleges, and the present Catholic University College, Dublin. To this plan, obviously, Trinity College would be strongly opposed, and it must be remembered it was over such a scheme that Mr. Gladstone was shipwrecked in 1873. 2. Another plan would be to found and endow a Catholic university, probably combining with it the Queen's Colleges of Cork and Galway, and to unite Trinity College and Queen's College, Belfast, in one Protestant university. In this way there would be two universities in Ireland. The Royal University would then, of course, cease to exist under such an arrangement, and its buildings would form the Catholic university. I am afraid, however, that Queen's College, Belfast, would never consent to such an arrangement, and probably Trinity College would not like the plan either. The old graduates of the late Queen's University of Ireland, many of them former students of Queen's College, Belfast, can never forget that it was to save Trinity College that their university was destroyed, and there is a tradition that the plan for its destruction was hatched within the walls of Trinity College, Dublin. Hence, with such a feeling still prevailing, the union of Trinity and Belfast Queen's Colleges in one common university would hardly be possible. 3. The third and, in the opinion of many, the most workable solution of the education question in Ireland would be to let Trinity College remain as it is, to establish and endow a Catholic university, and also to create a university of Belfast fully equipped and endowed with medical, Arts, theological, and engineering faculties. To such an arrangement there are two obvious objections, first, Can such a small country as Ireland support three universities? In reply, one has only to look to Scotland, where there are four universities, and to Wales, where, notwithstanding the number in England, the inhabitants are calling out for another university. The second objection is that such a plan would be merely denominationalism; but, under existing circumstances, however we may reget it, such a course is certainly gaining ground. If this third solution of the Irish education difficulty were carried out, of course the Royal University would cease to exist, and its present buildings could be handed over to the Catholics for their university. The University of Belfast would assist if Queen's College—which is in such a flourishing condition—and the Presbyterian colleges of Belfast, and Magee College, Derry, would form the theological faculty. The Presbyterian Church, to which the great majority of the Ulster students belong, could be granted under this scheme the right of appointing theological professors. I have ventured to sketch some plans for the solution of this vexed question of Irish university education. To all of them, undoubtedly, there are objections, but one thing is certain—the present arrangement, which is satisfactory to no one, cannot well continue much longer, and an attempt will probably be soon again made to settle the problem of Irish university education.

Extension of the Boundaries of Belfast.

At a special meeting of the city corporation held on Oct. 21st it was decided that a Bill should be presented to extend the boundary of Belfast so as to include the Parliamentary area. In future there are to be sixty members of the corporation and fifteen wards. Owing to the very rapid extension of the city in all directions there is, in many cases, no supervision either of the building or sewerage arrangements or any regulation of the frontage lines. In such places as Ligoniel and the district of the Connswater the bad drainage arrangements are constantly being discussed, but when these parts are taken within the corporate area there will be one sanitary authority, and so matters will more easily be adjusted.

Oct. 22nd.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Institut Pasteur: M. Pasteur's Successor.

THE administrative council of the Pasteur Institute met on the 16th inst. for the purpose of electing a successor to the directorate vacant by the death of M. Pasteur. The council is composed as follows: MM. Joseph Bertrand of the Académie Française, Jules Simon, Wallon, Duclaux, Maguin, and Christophe, Drs. Brouardel, Grancher, and Roux, Baron Alphonse de Rothschild, and the Vicomte Delaborde. M. Duclaux was unanimously promoted from the subdirectorship to the directorship, Dr. Roux being at the same time appointed sub-director in the place of M. Duclaux. An addition was made to the council in the person of M. Vallery-Radot, M. Pasteur's son-in-law; and M. Jean-Baptiste Pasteur, the late illustrious director's only son, was elected a member of the Assemblée (composed of thirty members, and under whose approbation the affairs of the Institute are managed by the council). The Institut Pasteur is the property of a company, but, having been recognised by the Government *d'utilité publique*, it is under the control of the State (Home Office). The Assemblée is made up of founders; by it the council is elected, the accounts passed, &c. The revenue is derived from the following sources: (*a*) the interest of 1,200,000 fr., balance of the sum of nearly 3,000,000 fr. publicly subscribed, about two-thirds of which was absorbed by the acquisition of the land upon which the Institute stands and by the building of the said Institute; (*b*) a subvention of between 20,000 fr. and 30,000 fr. made by the Agricultural Department for services rendered ("vaccinations" of animals against charbon, glanders, &c.); (*c*) a subvention (sum not mentioned) of the Ministry of Public Instruction to provide for the salaries of such officials as belonged formerly to the École des Hautes Études; (*d*) profits derived from the sale of vaccines supplied at a low rate to veterinary surgeons, these profits having been ceded to the Institute by M. Pasteur and by MM. Roux and Chamberland (the revenue from this source reaches about 20,000 fr. per annum; and (*e*) fees paid by the bacteriological students of the Institute. The anti-diphtheric department, directed by Dr. Roux under the dual control of the council of the Institute and the Ministry of the Interior, is an *annexe* of the Institute, but has a distinct budget. The headquarters of this department are at Garches (where Pasteur died) on a property ceded to Pasteur by the State. The serum is distributed gratis, according to the demands of the Ministry of the Interior, to the army, and to the hospitals and *bureaux de bienfaisance* of France and her colonies. The expenses are met by the interest of the public subscription (collected by the *Figaro*) and by a sum voted annually by Parliament (this year it amounted to 80,000 fr.). The serum is supplied to the public under the provisions of the Pharmacy Law, a small bottle being procurable at every druggist's for 3 fr. Any profit accruing from the sale will be devoted to the improvement of the particular *service*. The work done at the Institute comprises inoculations and lectures delivered by Drs. Roux and Metchnikoff, whose pupils are divided into two categories—those who are simply listeners and those who come to acquire the technique of bacteriology. There are, moreover, laboratories provided for investigators engaged in original research, the results of whose work are chronicled in the "Annales de l'Institut Pasteur." The teaching *personnel* is as follows:—Biological chemistry, M. Duclaux, who is besides Professor at the Faculty of Sciences, but who now gives his lectures at the Institute instead of at the Sorbonne, as was the case formerly. Rabies: Professor Grancher, with the collaboration of Drs. Charrin and Chantemesse. Sanitary bacteriology, "vaccinations," and practical applications: M. Chamberland. Morphological bacteriology: Dr. Metchnikof. Technical bacteriology: Dr. Roux. Finally, Professor Nocard of the Alfort Veterinary College superintends a veterinary *service* attached to the Institute. The Institute, opened in 1888, will continue its activity under the same constitution as under its late chief.

Some Curious Clinical Analogies.

In a recent lecture on Exophthalmic Goitre Professor Potain drew attention to the curious similarity existing between the symptomatology of that disease and a fit of passion. Look at a man under the influence of intense anger and you have an exact reproduction of the aspect of a sufferer from Basedow's disease—facial immobility, prominence of the eyeballs, fixity of gaze, trembling especially of the hands, palpitation of the heart, abundant sweating, sometimes diarrhœa and psychical disturbance reaching at times unconsciousness. What renders the analogy more marked is the fact that the onset of exophthalmic goitre has synchronised with a fit of passion. Professor Potain then remarked on the resemblance in many respects of Basedow's disease with Parkinson's (paralysis agitans). This neurosis he takes to be closely analogous to another physiological condition—terror. Thus in 1848, after the Revolution, there came under notice a large number of cases of paralysis agitans. Professor Potain graphically describes exophthalmic goitre as "congealed rage," and paralysis agitans as "congealed terror" (*colère figée* and *frayeur figée*).

ROME.

(FROM OUR OWN CORRESPONDENT.)

Winter Weather.

"'WINTER cities,' with a vengeance," was no doubt the remark of many an "arrival" who, having expected to bask in the warmth of a genial October, looked out yesterday on the snow-besprinkled Apennines. From the Agro Romano the heights beyond Rocca Priora and the flanks of Monte Gennaro appear arrayed in white, though Soracte remains bald and bleak as if determined to prove that only in the writings of Horace is it ever touched by snow. Curiously enough, it is the extreme spurs of the Southern Apennines that are most heavily visited by the premature winter; indeed, at Agnone in Sicily the thermometer had yesterday sunk to zero Cent. The bitter *tramontana* (north wind) meanwhile is sweeping over plain and city, enfilading the streets with "chilled shot" and forcing the thinly clad pedestrian within doors, whence he comes out, if at all, cloaked and muffled as if the ground on which he treads were a landslip from Siberia. Other cities than ours are even more fiercely assailed by the northern invader, and Florence, I hear, looks out on the uplands behind Vallombrosa and above Pistoia—nay, on Monte Morello itself—fleecy with winter. "Our Lady of Flowers" in ermine, as she appeared in February last, is doubtless a lovely and imposing object; but that she should affect that pose ere the autumn is well over is too much for her most thorough (I cannot say "warm") admirers. Italians, as a rule, are ill-prepared for such unseasonable visitations, and the sick-list and even death-rate from chest affections are apt to be abnormally large in consequence. The British tourist, *a fortiori* the British invalid, who contemplates a sojourn more or less prolonged in one or other of our winter cities, would do well, therefore, to bring plenty of warm clothing, as the arrangements for heating hotel or *pension* are not always satisfactory, and the stone floors, thinly carpeted or merely strewn with rugs, are fraught with danger to susceptible new-comers, particularly to young females. Catamenial disturbance, often of a very intractable kind, has thus been occasioned, while catarrhal affections, from the simple cold in the head (what Italians call *costipazione di testa*) to the gravest lesions of the mucous tract, respiratory or alimentary, are induced or aggravated by the same absence of comfort in draughty rooms or passages.

Congresses and Congressers.

To the information already given as to the Congress of Internal Medicine, which sits here from the 22nd to the 25th inst., I may add that the representation of the profession will be weightier, as well as more numerous, than on any similar occasion. Feletti of Catania, Massalongo of Padua, Sclavo of Turin, Giuffré of Palermo, Patella of Perugia, Rovighi of Bologna, Salomone-Marino of Messina, Masini of Genoa, Sgobbo of Naples, and Banti of Florence, all professors at these respective seats of learning, are a few out of many other delegates of the same standing, while as to the physicians in consultant or general practice their name is legion. The novel feature in the present congress is, as already stated, the delivery of clinical lectures in hospital (in this case the Santo Spirito) by past masters in their special subjects. Dr. Cardarelli, Professor of Clinical Medicine in Naples University, will discourse, with illustrative references, on Primary Sarcoma of the Pleura; Dr. De Giovanni of Padua on a Form of Congenital Hepatic Lesion; Dr. Grocco of Florence on the Psychical Stigmata of Hysteria (an interesting study of such cases as that of Louise Lateau); and Dr. Riva of Parma on the Cure of Empyema. The tendency to define and limit the subject-matter of these professional congresses explains this wholesome innovation on the old, promiscuous, and decidedly over-charged programme; while the announcement of the themes beforehand enables the Congressisti to reconsider or re-examine them in anticipation, and thus to profit the more from their treatment by experts. At Venice another important congress has been held on a subject of prime importance in Italy—Hydrology and Climatology. Her rich supply of mineral waters, and the variety, salubrity, and amenity of her climates are just beginning to be appreciated by her physicians and made practically available for the invalid. Gratifying progress in this latter direction was put *en évidence* at the congress, and, as to Venice in particular, the new drinking-water with which she has been provided, the baths, and the opening up of the Canal of Saint Mark being adduced as showing the advances made in sanitary resources by the Queen of the Adriatic. Another improvement of the kind was the restoration of the port of the Lido. This is the main entrance to the city from the Adriatic, but it was allowed to become so shallow by the silting up of its bottom that the water could not admit vessels of any considerable "displacement," while the currents were so few and so sluggish as to make the islands to the north quite malarious in hot weather. The cleansing and deepening operations effected by the "Genio Civile di Venezia" have changed all that; the largest ships can now enter the lagoons with safety, and the islands are as healthy and habitable in summer as in winter. All this is very reassuring to the travelling public and may be classed with the Disinfection of Baths, the guaranteeing of Purity in the Mineral Waters of Commerce, and such like matters discussed at the congress as proofs of Italy's hygienic, no less than political, "risorgimento." A curious topic, by the way, cropped up at this congress, Free Trade in Waters impregnated with Iodine Salts. Salt, or chloride of sodium, it is well known, is a Government monopoly in Italy. Now in such mountainous tracts as the Apennine range between Forli and Florence there are many salt springs containing iodine. These are under close surveillance for the salt they hold in solution; but, notwithstanding this, the peasantry contrive to get the water in considerable quantities and extract the salt for their own use. Their *modus operandi*, however, does not eliminate the iodine, and by their use of salt so iodised they often injure their health, insanity being in some cases induced. The subject is important enough to attract the attention of the Public Health Department, and its ventilation at the congress will doubtless contribute to remedial legislation in the matter. In our university yet another congress opened to-day, that of Dermatology and Syphilography. Its president is Professor Tommaso De Amicis of the Neapolitan school, and a number of interesting papers were read and discussed in the forenoon and afternoon sittings. Of these I may note, for such of your readers as are making special studies in the same direction, Professor De Luca's monograph on Some Attempts at Sero-therapy in Lepra; Dr. Ciarrocchi's on the Absolute Necessity of Depilation in the Cure of Favus; Dr. Breda's on the Frambœsia of Brazil; Dr. Ciarrocchi's on Exudative Pleurisy during the Roseolar Stage of Syphilis; and Dr. Pini's note on Acute Psoriasis. Other papers are announced for tomorrow, and these, as reproduced in the officially revised "Atti" of the congress, will doubtless, like their predecessors, afford proof of the advances made by Italy in this very important branch of the healing art. I might wind up the list of medical or quasi-medical congresses held this month throughout the kingdom by a note on the Congress of Midwives (*Levatrici*) just concluded at Florence. But the interest attaching to this, though very real of its kind and sufficient to attract a large assemblage of *sages-femmes*, was rather social than scientific in its tenour, and even in the social aspect was of too local a character to merit more than this passing reference.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

The General Hospital.

THE proposal to transfer the General Hospital to the site of the Lunatic Asylum has now been set aside through unforeseen circumstances. The authorities were disposed to sell the site of the Lunatic Asylum to the State and to acquire the so-called Kobenzl (a hill in the environs of Vienna) for the purpose of building a new establishment there, as in this locality, which is remote from the bustle of the city, the asylum would have agreeable surroundings and, on the other hand, the General Hospital would have been a gainer by the change of situation. But pecuniary difficulties seem to have arisen when the matter came before the Finance Board, for although the prescribed time (Sept. 30th) has already passed, the Board has not yet made any sign of coming to a decision. As this project is now at an end the only alternative is the acquisition of the barracks next to the hospital; but in this case the clinics of the present hospital would have to be built elsewhere for the additional area would not be sufficient.

The Treatment of Diphtheria.

According to statistical returns published by the secretary of the Anna Hospital for Children the cases of diphtheria during 1894 numbered 914, with 425 deaths, being a mortality of 46·24 per cent. Among 760 cases treated by the old methods there occurred 385 deaths, yielding a mortality of 50·65 per cent., but since the introduction of serotherapy in October, 1894, there have been 40 deaths among 159 children affected with diphtheria, or a mortality of 25·15 per cent. Stenosis of the larynx in croup and diphtheria was treated by O'Dwyer's intubation and tracheotomy, either separately or in combination. In the cases where the stenosis was very urgent only tracheotomy was performed. Of 108 cases treated only by intubation 89 recovered and 19 died, being a mortality of 17·6 per cent. Both intubation and subsequent tracheotomy were performed in 121 cases, among which 28 recovered and 93 died, being a mortality of 76·8 per cent. In 166 cases tracheotomy only was performed, and among these there were 161 deaths, being a mortality of 97 per cent. The total number of cases with diphtheritic stenosis of the larynx which were operated on amounted to 395, with 122 recoveries, being a proportion of 30·8 per cent.

Professor Albert on Medical Study by Women.

The pamphlet on the Medical Education of Women published by this far-famed surgeon and teacher has not failed to cause a general sensation. The writer seeks to prove on physiological grounds that women are not well fitted to practise medicine; but his arguments ultimately lead to the conclusion that women are unsuited for any scientific occupation or pursuit, and should devote themselves to domestic duties and the exercise of the maternal functions. Under altered conditions of education women may succeed in approaching the comparatively high intellectual level of men; but they will nevertheless not be logical, for the impulsive faculty predominates in them, whereas the reflective and methodical habit of mind is peculiar to men. After this unflattering decision the writer discusses the question of the admission of women to medical study, and appeals to a pamphlet by the late Karl Vogt of Geneva, in whose opinion the small success of women as medical practitioners is due to their insufficent preparatory studies. Women, he concludes, are not competent to undertake the difficult tasks of medical practice, but they may do useful service in midwifery and operations. For this purpose they should be instructed in the elements of physics, chemistry, anatomy, physiology, surgery, and midwifery.

The Health of the Army.

According to the official report the number of recruits in 1893 amounted to 764,222, of whom 74·9 per cent. were rejected, as against 77·6 in 1892 and 75·3 in 1891; 2·3 per cent. were disqualified because of insufficient stature, and 51·7 per cent. because of weakly development of body, while 20·9 per cent. were declared absolutely unfit for service. The stature of 153 cm. (= 5 ft. 1 in.) was reached by 3·6 per cent. The details of the rejections for disease and deformity are the following; 0·49 per cent. for scrofula, 1·98 per cent. for diseases of the eye, 2·66 per cent. for varix, 2·39 per cent. for goitre, 2·21 per cent. for hernia, 0·81 per cent. for varicocele, 1·69 per cent. for knock-knee, 1·4 per cent. for flat-foot, and 2·18 per cent. for deformities of the thorax, the spinal column, and the skull. Insufficiency of stature existed in the following proportions among the men of the several nationalities: 1·6 per cent. for the Croats, 2·6 per cent. for the Hungarians, 2·8 per cent. for the Germans, 3·5 per cent. for the Bohemians, 4·3 per cent. for the Roumanians, 6·7 per cent. for the Poles, whereas the cases in which the requisite standard was attained respectively amounted to 27·4, 26·7, 24·2, 23·8, 34·8, and 22·2 per cent. During 1893 the rate of invaliding was 8·79 per cent. of the soldiers against 9·11 in 1892 and 8·91 in 1891. Scorbutus formed 0·23 per cent. of all the registered diseases, arthritis 0·81 per cent., scrofula 0·13 per cent., phthisis 0·32 per cent., trachoma 0·77 per cent., pneumonia 0·85 per cent., pleurisy 0·44 per cent., angina 4·59 per cent., syphilis 6·54 per cent., and diseases of the skin 21·58 per cent.: the report also mentions 41 cases of cholera. The number of deaths amounted to 1172, being a mortality of 0·39 per cent. of the army, against 0·45 per cent. in 1892 and 0·4 in 1891, the highest monthly rate being registered in April and the lowest in August. Suicides numbered 321, being equal to 0·1 per cent., and there have also been 109 cases of attempted suicide and 76 of self-mutilation. The report confirms the well-known fact of the increasing degeneration of the Galician population and the prevalence of venereal disease, attributable to service in Bosnia, where syphilis is raging.

Unhealthy Houses in Vienna.

Those who expected that the new Building Act would become law in 1894 have been disappointed, and meanwhile houses have been erected in contravention of the rule that 15 per cent. of the site should remain uncovered by buildings. The housing of the masses, therefore, remains as unsatisfactory as ever, and will not be improved as long as the poor are at the mercy of speculators eager for exorbitant profits. Under these circumstances it is not surprising that many persons have to rent cellar dwellings and other places unfit for habitation. Another abuse which frequently occurs under the present system is the premature occupation of newly built houses. It is well known that brickwork requires a year for effectual drying and for the passage of air through the interstices to become established, but nevertheless, and in spite of legal prohibition, tenants enter into possession almost before the scaffolding is removed. Chronic ill-health among children, scrofula, infectious diseases, early death, and the initiation of youth into vice are some of the evils resulting from overcrowding and unwholesome dwellings.

Cholera in Galicia.

During last week 19 cases of cholera and 18 deaths have been reported from the districts of Tarnopol, Kamionka, and Trombosola, making a total of 113 cases with 77 deaths since the commencement of the outbreak.

Oct. 21st.

RUSSIA.

(FROM OUR OWN CORRESPONDENT.)

New Regulations for the Russian M.D. Degree.

CONSIDERABLE changes are about to be made in the Russian degree of Doctor of Medicine, both in the methods by which it is obtained and (so far as Government authority can alter the status of a degree) in the general standing of the M.D. degree. The proposed alterations were suggested some years ago by the Ministry of Education, and in the meantime were submitted to the criticism of the medical faculties of all the Russian Universities and the Imperial Army Medical Academy. Finally the scheme came, as all such schemes must, before the Medical Council, the final authority in all medical matters. The Council has decided to make the following changes. The degree of M.D. will no longer be an *utcheno-practitcheski* degree as hitherto—that is to say, it will cease to be classified among others as a "scientific-practical" degree, but will be purely *utchenui*—that is, "scientific" or "learned." Consequently, Doctors of Medicine will cease to be classed as belonging to an *utcheno-sluzhebnui* calling. To make this quite clear would necessitate a complete account of the system of *tchins*, castes or ranks, which obtains in Russia, and by which the whole nation is divided and subdivided into groups and each person labeled according to his calling and rank in it. Briefly the result of the new change appears to be that, as the above-mentioned term signifies rather the official rank (length of

Digitized by Google

service &c.) of the individual than the extent of his scientific attainments, holders of the M.D. degree will be outside such official designation altogether. The conditions under which the degree will in future be granted are these: The candidate must have obtained the Russian diploma of "Vratch" (or medical practitioner) at least three years before the examination for the M.D. is concluded. This examination, which covers many subjects, must not extend over two *semestres*. The candidate who passes this must within the next five years present and defend a thesis on some professional subject; if he does not do so, but should still desire to obtain the degree after a longer period than five years, he has to undergo a fresh examination. The examination includes such general subjects as anatomy (macroscopic and microscopic), physiology, pathological anatomy and histology, the history of medicine, and general hygiene; but it is more particularly directed to the special branch of the medical sciences which the candidate may choose. Specialism is, indeed, the keynote of the new regulations. There are seventeen subjects or branches of specialism named; these are anatomy, histology, physiology, physiological chemistry, pathological anatomy and histology, general pathology, pharmacology, pharmacy and pharmacognoscy, internal diseases, nervous and mental diseases, venereal and skin diseases, surgery, ophthalmology, midwifery and gynæcology, disease in children, hygiene, and finally legal medicine. There is little doubt that under the new regulations the degree of M.D. will be considerably harder to obtain than it is now; and it is now by no means easy. What seems likely to be questioned is the wisdom of making it practically inaccessible to any but specialists. On the other hand, specialism meets with high approval and success in this country and is carried to an extent undreamt of in England.

Cholera in Russia.

The following table completes the statistics of cholera in Russia up to the present; it is a continuation of the table in my last letter:[1]—

	Cases.	Deaths.
In Volhynia.		
Between Aug. 19th and Aug. 26th	4273	1668
,, Aug. 27th ,, Sept. 2nd	3554	1417
,, Sept. 3rd ,, Sept. 9th	2330	903
,, Sept. 10th ,, Sept. 16th	1919	798
In Kief.		
Between Sept. 3rd and Sept. 9th...	16	3
,, Sept. 10th ,, Sept. 16th...	41	18
In Podolia.		
Between Aug. 20th and Aug. 26th	35	11
,, Aug. 27th ,, Sept. 2nd	16	8
,, Sept. 3rd ,, Sept. 9th	28	15
,, Sept. 10th ,, Sept. 16th	9	3
,, Sept. 17th ,, Sept. 23rd	0	0
In Primorskaia or Maritime Province.		
Between July 1st and Aug. 29th...	74	54
,, Aug. 30th ,, Sept. 5th	8	4
,, Sept. 6th ,, Sept. 12th	8	11
,, Sept. 13th ,, Sept. 18.h	2	1

It will be seen that the epidemic is diminishing everywhere except in the government of Kief, where it is, or was, increasing. It is present in only one *uyezd* of the government—that of Berditchef. In Podolia, it will be observed, the epidemic is extinct.

The late Tsar and M. Pasteur.

In connexion with the death of Pasteur it may be of interest to recall the fact that one of the most munificent of the original donors to the Institut Pasteur was the late Tsar, Alexander III., whose donation was no less than 100,000 fr. Many Russian learned societies and some lay corporations sent representatives to the recent funeral ceremony in the Rue Dulot.

Causes of Death in the Medical Profession.

The last monthly report of the Medical Department contains a supplement of some interest. This is a tabular statement of the cause of death of 1400 medical men who have died in Russia during the last six years. The most striking figure in the table is the 457 deaths from infectious diseases—that is to say, that nearly one-third of the total number of deaths were due to disease contracted (presumably) in the course of professional duty. These 457 deaths include 95 from typhus fever, 193 from pulmonary consumption, 28 from typhoid fever, 10 from diphtheria, and 3 from small-pox. From diseases of the respiratory organs there were 52 deaths, of the circulatory organs 122, of the alimentary system 39, of the excretory system 35, of the nervous system 120, and, finally, from suicide 50.

St. Petersburg, Oct. 7th (19th).

[1] THE LANCET, Oct. 5th, 1895. The dates in the table are all according to the Old Style.

EGYPT.

(FROM OUR OWN CORRESPONDENT.)

Cholera at Damietta.

TWELVE years ago, on June 22nd, 1883, cholera was discovered at Damietta, a seaport town of about 40,000 inhabitants of the strictly conservative order of Mussulmans. Now, after many summers during which cholera has been fruitlessly searched for by clinical and bacteriological experts, the fiend has suddenly reappeared. So far it is unknown whence or why, and it has not yet been possible to trace any connexion between it and the return of the pilgrims from Mecca, where there undoubtedly was cholera in the summer months. But it is satisfactory to state at once that its discovery has not, as in 1883, been preceded by a long period of premonitory diarrhœa. There is a history of seven outbreaks of cholera in Egypt since 1831, and every one of those occurred during the summer, usually beginning in June and ending in October—i.e., appearing when the Nile is low and the drinking-water foul, and vanishing gradually when the Nile flood has been some little time at its height and has had time to carry all impurities from canals and wells by its majestic flow towards the sea. To find a parallel to the present year I must go back to 1837, when there was a short mild outbreak of cholera in September, but this, according to Hirsch and other observers, was part of a continuous progress through Tripoli and Tunis to Abyssinia and Zanzibar. The 1837 disease has left no official traces behind it in Egypt, and I can only hope that the present scare will be as little harmful to the welfare of this country. On Oct. 12th news reached the Sanitary Department in Cairo, from their inspector at Damietta, that he had heard of two cases of suspicious diarrhœa and vomiting, and that in one the patient was already dead. Instructions were at once telegraphed to him to perform a necropsy and preserve the intestines for Dr. Kauffman, who was immediately sent to Damietta with Dr. Pinching. Dr. Kauffman reported next day that he had found no bacilli in the fresh fæces, but that they existed in small numbers in peptone cultures. He sent at the same time a special messenger with some of the suspected material to Dr. Bittar, a disciple of Professor Koch, who shares with Dr. Kauffman the highest bacteriological reputation in Egypt. Dr. Bittar, working in his laboratory in Alexandria, telegraphed independently that he also failed to find any comma bacilli until after a peptone culture. Dr. Kauffman, who studied cholera clinically at Hamburg, also stated that the cases in the hospital wards and in the post-mortem room were not unlike mild cholera. The English authorities determined from the outset to act energetically and openly. The Quarantine Board and the press were informed, Dr. Rogers Pasha was recalled from leave in Europe, and all possible sanitary measures were put in force at and near Damietta. On Oct. 13th there was a second death, and on the 14th two others, all confirming the diagnosis only too certainly. On Oct. 15th at 2 A.M. characteristic colonies on gelatine were seen of the first two cases, and to-day I, with Dr. Armand Ruffer, have seen bacilli from the sixth death, which occurred yesterday. A rice-water stool was taken direct from the ileum soon after death and furnished bacilli on peptone, but in very small quantities. It is by no means conceded in Egypt that the comma bacillus is the cause of cholera, but it is, of course, recognised that it is a constant companion, if not more. Altogether there have now been seventeen cases, including eight deaths, all living in one of the worst quarters of Damietta and taking water from an unclean canal in the neighbourhood. Now that the existence of the disease is proved the water-supply is of the greatest importance. I am able to state upon the highest authority in Egypt that Damietta is now having its best possible water-supply, though its poorer inhabitants may have to be prevented by force from making use of that which is bad. The Nile flood reached Damietta this year at the end of July about ten days earlier than usual, and even before that there was a very fair supply of water all through the

Digitized by Google

summer, for the Nile was at an exceptionally high level. When the Nile is low the water becomes salt because it is then below the sea level, and the inhabitants have to depend upon a large cistern which has lately been made water-tight and is regularly cleaned out. This is sufficiently large to supply the town for two months. Moreover, since 1890 a new circular canal has been dug, bringing Nile water from near Cairo, and this is now at its height. About the same date the *cloaca maxima* of the town was filled in and converted into a road. During the latter half of September there was a mysterious illness in the village of Ekhwa, and also in the eastern Delta, but many miles from Damietta; twelve sick people were treated and as many as nine died. The sick and the necropsies were seen by Dr. Kauffman, who failed to find any evidence of cholera, bacteriologically or otherwise. They were also seen by Dr. Hamdy Bey, who, as sanitary inspector of Cairo in 1883, had a large experience of cholera. Both declared officially that the disease was not cholera, and they believed that it was due to some ptomaine poisoning. The inhabitants of this village lived chiefly at this time upon dates, which they were gathering all day, and upon "fisikh," a stinking fish of which the natives are very fond. Since the reports from Damietta I have interviewed both these medical men, and they are still quite firm in their belief that the September illness was not cholera.

Cairo, Oct. 16th.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Election of the Staff of the Melbourne Hospital.

ON Aug. 15th last the whole of the honorary medical staff of the Melbourne Hospital, eighteen in all, were elected by the subscribers to the institution for a period of four years. The polling was conducted in a large hall in Collins-street, the pavement in front of which, and for a considerable distance beyond, was blocked all day by an eager crowd, and the public excitement was even greater than that seen at a political contest. The partisans and touts of several of the candidates wore colours and distinguishing badges, and were most persistent in pushing the claims of their respective candidates. The proceedings, as a whole, were anything but calculated to raise the profession in the eyes of the public, and in individual instances were most offensive, and even ludicrous, as, for instance, when a small donkey-cart, holding a diminutive boy, was driven up and down the street placarded with large posters asking for votes for two of the candidates, both of whom, however, repudiate the device. A remarkable feature was the number of ladies who were present working for different candidates, while a most discreditable one was the fact that between twenty and thirty cases of impersonation of voters occurred. For months past (as explained in a previous communication) candidates and their friends have been conducting a most vigorous canvass, personally and otherwise, and it is an open secret that money was spent freely in manufacturing votes. It was supposed that a by-law passed a few months ago would have prevented this; but some means of evading it must have been discovered, as the president of the hospital stated, in a letter to the press, that 130 people in Adelaide voted by proxy and for one candidate. It must not be supposed that all the candidates resorted to these undignified and discreditable electioneering dodges, and it is gratifying to know that those members of the old staff who refrained from making a personal canvass and conducted their electioneering in a quiet and honourable manner were not only re-elected, but in most instances occupied good positions at the poll. The results were as follows, all the members of the old staff seeking re-election to their former positions being returned, their names being indicated in each case by an asterisk:—

As has happened after previous elections, proposals are now being made for altering the method of election. A Bill was introduced into the Legislative Council to appoint an electoral college for all the hospitals in the colony, but the Bill was not even voted on, so evident was the opposition to it. The Medical Society of Victoria at its last meeting decided to hold a conference with the other medical societies for the object of devising some better method of election. In the past, however, the difficulty has not been in devising schemes, but in getting them carried into effect.

Fatal Case of Abortion by a Quack.

Reference has already been made to the success and effrontery with which quackery is practised in Sydney. One of the fraternity, however, would appear recently to have gone a little too far, and in consequence is now lodged in gaol on a charge of murder. The first discovery in the case was rather sensational, a packing case being found in a principal street in Sydney containing the mutilated remains of a young woman. The inquiries of the police soon enabled them to get the body identified as that of a girl who had left her mother's home and went to Sydney with the object of getting abortion procured. It would appear that she went to the quack in question, who is alleged to have operated, with the result that she developed peritonitis and died. He then is said to have made a crude post-mortem examination and attempted to dispose of the remains in the manner described, which led to his speedy arrest.

Hydatid Cysts: their Treatment, Diagnosis, and Prevalence

Hydatid disease continues to occupy the attention of the profession in Australia. Mr. Charles Ryan of Melbourne has recently read two papers dealing with its surgical treatment. In the first paper two cases of multiple hydatids of the abdomen were described. In one case eighteen cysts were dealt with in four separate operations. At the first operation thirteen cysts in the omentum were removed, the portion of omentum containing them being ligatured and removed *en masse*; while another cyst growing from the pelvic peritoneum was evacuated, the cyst removed, and the adventitial sac sutured and dropped back into the abdominal cavity and the parietal wound closed (Bond's method). This cyst suppurated and had to be opened and drained, and another cyst pressing on the rectum was opened through the cyst first treated. Two other cysts on the other side of the abdomen were treated by Lindemann's operation and drained. The patient was desperately ill for a time, but recovered perfectly. In the second case fifty cysts in all were treated in six successive operations. Eighteen omental cysts were completely removed at the first operation. At the second seven further omental cysts were removed and two cysts in the liver treated by Lindemann's method. At the third operation two more hepatic cysts were treated in the same way. At the fourth operation five cysts in the mesentery were removed and three were incised and dropped back without suture of the adventitia. At the fifth operation a cyst on the upper surface of the liver was opened through the pleural cavity after excision of portion of a rib; the cyst was extracted and the wound closed without drainage or suture of the adventitia. Finally, at the sixth operation a splenic cyst was opened from the abdomen and treated in the same way. A good deal of constitutional disturbance followed the first four operations, but not the last two. In his second paper Mr. Ryan related four further cases of hepatic cyst treated by the intra-peritoneal method, without suture of the adventitia, and with immediate closure of the abdominal incision. All did well, and in three recovery was much more rapid than after Lindemann's operation. In one case some constitutional disturbance occurred, and eight days afterwards bile was evacuated through the wound and continued to discharge for three weeks. As the result of his experience Mr. Ryan is a strong advocate of the method of treatment adopted in these

Digitized by Google

cases, and says that "Lindemann's operation may now be relegated to the past for simple and uncomplicated cases, and be confined to suppurating and a few exceptional cases." He also points out the advantage of dealing with multiple hydatids in several successive operations when an attempt to remove too many at once would prove fatal. With this opinion surgeons who have had experience of these cases will agree, but the discussions on the two papers and on previous occasions show that there is far from unanimity as to the general applicability of the intra-peritoneal method, and difference of opinion exists as to its dangers and as to what happens when hepatic cysts are healed in this way. Some maintain that the edges of the incision in the adventitia become apposed to the abdominal incision, and that if serum or bile be effused into the adventitial sac the effused fluid will make its way out through the parietal incision and not into the peritoneal cavity. Others maintain that the fluid will escape into the peritoneal cavity, but will do no harm, being rapidly absorbed—i.e., if aseptic. Several cases have now been reported which show that bile does escape, and so far it has always, so far as is known, made its way out through the parietal incision and without doing serious harm. Since Mr. Ryan read his paper, however, he has himself operated by the intra-peritoneal method on a large cyst in the left lobe of the liver, with a fatal result from septic peritonitis. At the post-mortem examination the adventitial cyst was not near the incision in the abdominal wall, and was moderately distended with dirty grumous fluid similar to that which occupied the general peritoneal cavity. Dr. Fiaschi of Sydney contributes to the August number of the *Australasian Medical Gazette* a note on the value of "Santini's hydatid resounding sound" obtained by percussing a hydatid cyst while auscultating it. Dr. Fiaschi has verified the fact that the sound exists, and regards it as valuable, not only in helping to diagnose hydatid from other tumours, but in distinguishing single from multiple cysts. At the last meeting of the South Australian Branch of the British Medical Association Dr. E. C. Stirling of Adelaide read a paper on the Relative Prevalence of Hydatid Disease in the various Australasian Colonies, compiled from figures supplied to him by the different hospitals. It appears that hydatid disease is most prevalent in South Australia, where practically 1 out of every 100 patients admitted to hospital suffers from it. Victoria comes next with a percentage of 0·64, New South Wales has a percentage of 0·57, Tasmania 0·52, Western Australia 0·23, New Zealand 0·19, and Queensland 0·07. The average for all the colonies is 1 hydatid for every 206 in-patients. There is a special concentration of the disease in the south-eastern district of South Australia and the western district of Victoria. From a comparison of these figures with those compiled by the late Dr. Davies Thomas in 1884 it appears that there is a substantial increase in the prevalence of the disease, though the increased ratio is also probably to be accounted for to some extent by the disease being more frequently recognised.

Phthisis in Australia.

Dr. G. L. Mullins of Sydney has contributed to the August number of the *Australasian Medical Gazette* a paper bristling with statistics as to the prevalence and distribution of phthisis in the Australian colonies. He controverts the statement of Hirsch that "the reputation that Australia used to enjoy for the rarity of consumption and for the favourable influence of its climate upon the course of the malady has of late been shown to be a mistaken one." Comparing the death-rate from phthisis both per 100 deaths from all causes and per 1000 living inhabitants of Australia with other countries, Dr. Mullins shows that Australia has by far the lowest rate, and that the capital cities of that continent have a much lower rate than European cities. Further, it appears that phthisis is decreasing in prevalence in Australia. From the returns of Queensland—the only colony from which suitable returns can be procured—it appears that the Australian born population is not subject to phthisis. At the last meeting of the New South Wales Branch of the British Medical Association Dr. Sydney Jones advocated the establishment of a "farm hospital" for the treatment of cases of phthisis in its early stage. The buildings should be of an inexpensive kind, surrounded by a large area of land to be cultivated by the patients, and in this way it might be partially self-supporting. He objected to the mixing of early and advanced cases of phthisis in the same hospital.

Obituary.

THOMAS GROOM, F.R.C.S. ENG.

BY the death of Mr. Groom of Whitchurch, who passed quietly away on Oct. 7th, the county of Salop has lost its senior medical practitioner, a highly respected veteran, whose talents had for more than sixty years been devoted to the relief of suffering. He belonged to a very old Shropshire family, being the fourth son of the late Mr. John Groom, formerly of Hardwicke Grange, and he was born at Wolverley Hall in the same county. Hardwicke was the residence of Lord Hill, the famous general of the Peninsular War, who also fought at Waterloo, and was Commander-in-Chief to His Majesty George III., and it was there that he died. Mr. Groom commenced the study of medicine by becoming an apprentice to the late Dr. Gwynne of Wem. He subsequently studied at Guy's and St. Thomas's Hospitals, and after passing the usual examinations gained the diploma of the Society of Apothecaries in 1833, and became a Member of the Royal College of Surgeons of England in 1834. Having commenced practice at Whitchurch in 1834, he for many years enjoyed a large and lucrative practice in the town and neighbourhood, and in 1861 was admitted an Honorary Fellow of the Royal College of Surgeons of England, but of late years he retired from the more active duties of his profession. The deceased endeared himself to a large circle of friends, by whom he was much esteemed, and his cheerful disposition and genial hospitality will long be remembered. He would have been eighty-six years of age had he been spared a few weeks longer to see Nov. 21st, and was a widower, having been twice married, but has left no family. He was an ardent sportsman, and as showing the abundance of game in the neighbourhood of Whitchurch in the "good old days," as compared with the present time, it may be noted that one forenoon in September in the "forties," before the days of breechloaders, he killed with one barrel thirty brace of partridges. So greatly was the deceased respected that when his funeral took place, on Oct. 10th, along the entire route from his late residence to the parish church there was not a house where the blinds were not drawn down or the shutters closed. Many beautiful wreaths and mosses were deposited on the grave by relatives and personal friends.

FREDERICK BERNARD BETTS, M.R.C.S. ENG., L.R.C.P. LOND.

ALL those members of the profession who came in contact with Mr. F. B. Betts will be deeply grieved to hear of his untimely death at Antofagasta, Chili, on Sept. 4th. Mr. Betts entered the medical school of the Westminster Hospital in 1884, and worked with unremitting zeal until he became qualified to practise in 1889, distinguishing himself by taking no small number of prizes. He held in the hospital all the resident posts until failing health sent him for three voyages to South America as surgeon to the R.M.S. *Iberia*. On his return with recovered strength he acted as resident medical officer at Queen Charlotte's Lying-in Hospital, after which he left England for the last time on his acceptance of a post as surgeon to the Huanchaca Silver Mine and Railway Company at Antofagasta. Possessed, as he was, of an exceptionally cheerful disposition, he quickly won the hearts of those among whom he had elected to dwell, and his early death—Mr. Betts was but twenty-eight years of age—was received with universal dismay amongst European residents and Chilians alike. The *Chilian Times* of Sept. 11th paid a touching tribute to his memory in a long article, concluding: "Although but little more than two years resident in Antofagasta, the universal grief manifested at his death and at his grave testified how much he was respected and beloved. His memory will linger long in many a grateful heart."

JOHNSON MARTIN, L.F.P.S. GLASG., L.S.A. LOND.

THE many friends and acquaintances of Mr. Johnson Martin, of Great Lever, near Bolton, have been deeply moved by his death, which took place on Sept. 22nd at his residence, Carlisle-terrace, Moses Gate. He was the son of

Digitized by Google

Dr. Robert Martin, and was born at Tyldesley in 1821. Having resolved to follow his father's profession, which two of his brothers had already entered, he studied at the Pine-street School of Medicine, Manchester, increased his knowledge by apprenticeship to one of his brothers, and qualified as L.S.A. in 1851. After a further period of study at King's College he obtained the diploma of the Faculty of Physicians and Surgeons of Glasgow in 1857, and before many years was in the enjoyment of an extensive practice at Farnworth, near Bolton, from which place he removed to Moses Gate in 1881. Mr. Martin took an active part in local politics and public business for more than thirty years, contributed several articles to periodical medical literature, and in 1883 wrote a report on Over-pressure and Home Lessons to the Local Government Board. He has left a widow and family, one of his sons being in the medical profession. At the time of his death he was President of the Bolton Medical Society.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The death of the following eminent foreign medical man is announced:—Dr. L. T. Tumas, formerly Professor of Internal Medicine in Warsaw, from phthisis at Yalta in the Crimea. He had been a distinguished student in the St. Petersburg Medico-Chirurgical Academy, where he held office under the late Professor Botkin and was assistant physician in charge of Professor Manassein's wards. He had published papers on phthisis, on the vomiting centres, and other subjects.

Medical News.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS AND SURGEONS.—The following gentlemen passed the First Examination of the Board under the four years' regulations in the subjects indicated:—

Chemistry, including Chemical Physics:

Anderson, Lewis Pemberton, University College, Liverpool, and Owens College, Manchester.
Ashe, Arthur Ogilvie, King's College, London.
Duncan, James Simpson, Westminster Hospital.
Duncan, John Marie Sloane, London Hospital.
Edwards, William Howard, Guy's Hospital.
Read, Walton Rix, private study.
Wolverson, John Archibald, Mason College, Birmingham.

Materia Medica:

Ahrens, Henry Augustus, King's College, London.
Argles, Robert Lendon, St. Mary's Hospital.
Beverley, George William Bertram, University College, Bristol.
Butler, Thomas Langton, St. Mary's Hospital.
Cater, Joseph, King's College, London.
Chidley, Thomas James, Carmichael College and Royal College of Surgeons, Dublin.
Duncan, George Ernest, Guy's Hospital.
Edwards, William Howard, Guy's Hospital.
Ellis, Martin Francis, Yorkshire College, Leeds.
Fox, Campbell Tilbury, University College, London.
Haynes, George Secretan, St. Bartholomew's Hospital.
Henery, John Philip Edmund, St. George's Hospital.
Hopkins, Edward Lewis Nathaniel, Middlesex Hospital.
Lennane, Alfred James Andrew, University College, London.
May, Walter John, Charing-cross Hospital.
Meade, Frank Elliott, St. Bartholomew's Hospital.
Mussellwhite, William, Guy's Hospital.
Nicholls, Ernest Albert, London Hospital.
Norrington, Henry Lawrence Weekes, University College, Bristol.
O'Flaherty, Austin Romnald, London Hospital.
Silvester, William George, Mason College, Birmingham.
Wilcox, Richard Loy, University College, London.
Williams, William John Howard, St. Mary's Hospital.
Youell-Carter, Oliver Charles, Charing-cross Hospital.

Elementary Anatomy and Elementary Physiology:

Bennett, Percy Moore Septimus, Middlesex Hospital.
Beringer, Fritz John Alfred, London Hospital.
Dutton, William, Owens College, Manchester.
Holroyde, Alfred, Yorkshire College, Leeds.
Walmisley, Nicholas, St. Bartholomew's Hospital.
Whyte, Frederick William, Queen's College, Belfast, and Mr. Cooke's School of Anatomy and Physiology.

Elementary Anatomy only:

Agnew, Samuel Skelton, Queen's College, Cork and Belfast.

Elementary Physiology only:

Nelson, William Ernest, Cambridge University.

The following gentlemen passed the First Examination of the Board under the five years' regulations in the subjects indicated:—

Chemistry and Physics:

Alderson, Francis Bellairs, Firth College, Sheffield.
Bell, Robert John, Charing-cross Hospital.
Bennett, William Frederick Cockayne, Firth College, Sheffield.
Beverley, Kenneth Harold, University College, Bristol.
Brunton, Arthur Greene, Mason College, Birmingham.
Carter, George Archibald, Royal College of Surgeons, Edinburgh.
Causton, Albert Edward, Guy's Hospital.
Clarke, Arthur Allen Faster, St. Thomas's Hospital.
Cox, George Ralph, School of Science, Cheltenham.
David, Archibald Sinclair, London Hospital.
Davis, Alexander Montagu, Mason College, Birmingham.
Devitt, Herbert Pye-Smith, University of Cambridge.
Dunstan, Robert, London Hospital.
Francis, William Varè Chalmers, Westminster Hospital.
Fyffe, Robert James, Firth College, Sheffield.
Gauld, Reginald, London Hospital.
Goble, Edwin Wallace, Guy's Hospital.
Goodwin, William Richard Power, St. Mary's Hospital.
Green, Samuel Morris, University College, Liverpool.
Gribbell, William Ernest, St. Mary's Hospital.
Hagon, Albert, University College of South Wales, Cardiff.
Haig, Thomas Baker, St. Bartholomew's Hospital.
Hall, Robert William Basil, Guy's Hospital.
Harris, Thomas Arthur Ball, Firth College, Sheffield.
Harrison, Reginald Temple, St. George's Hospital.
Hearn, Edward Michael William, London Hospital.
Hopkins, William George, St. Mary's Hospital.
Kerfoot, Stanley James, London Hospital.
Lamb, Ralph, University College, Liverpool.
Leggatt, Claude Edward Heisch, St. Mary's Hospital.
Lewis, Arthur Cedric, Guy's Hospital.
Loosely, William Henry, Guy's Hospital.
Mead, Edgar Preston, London Hospital.
Moses, David Assur Henry, St. Bartholomew's Hospital.
Narramore, Edward Giles, School of Science and Technology, Liverpool.
Passmore, William Henry, Charing-cross Hospital.
Porter, Charles Robertson, London Hospital.
Reilly, Percy George, London Hospital.
Rowland, Frank, Mason College, Birmingham.
Semmence, Ernest Edward, Royal College of Surgeons, Edinburgh.
Speirs, William Clark, St. Mary's Hospital.
Wells, Hardy Vesey, St. Mary's Hospital.
Woodyatt, Henry Constantine, Owens College, Manchester, and University College, London.
Young, Thomas, St. Bartholomew's Hospital.

Practical Pharmacy:

Asten, Walter, Mason College, Birmingham.
Beale, Hanway Richard, St. Thomas's Hospital.
Beale, Joseph Richard, St. Thomas's Hospital.
Brown, Thomas Warren, St. Bartholomew's Hospital.
Bradley, Richard Walter, St. Mary's Hospital.
Capper, Harold Selwyn, University College Hospital.
Cornish, Philip Alfred, Middlesex Hospital.
Crawley, Herbert Edward, Oxford University.
Cunningham, John Francis, St. Thomas's Hospital.
David, Archibald Sinclair, London Hospital.
Edington, Ernest Adolphus, University College, London.
Fyffe, Robert James, Firth College, Sheffield.
Hawker, Herbert, University College, London.
Hearn, Edmund Michael William, London Hospital.
Hoyle, John, Owens College, Manchester.
Jeaffreson, Dudley, St. Bartholomew's Hospital.
Ruttledge, William Edward, University College, London.
Scott, Claude Sigismund, St. Bartholomew's Hospital.
Smith, Thomas Shalden, St. Mary's Hospital.
Stephens, Henry Zouch, St. Thomas's Hospital.
Twort, Frederick William, St. Thomas's Hospital.
Vine, Alfred Bertram, Middlesex Hospital.
Wood, Charles Herbert, University College, London.

Elementary Biology:

Barnes, George, St. Mary's Hospital.
Brangwin, Charles Harold, Guy's Hospital.
Bryan, Clement Arthur Douglas, Guy's Hospital.
Carter, George Archibald, Royal College of Surgeons, Edinburgh.
Cope, Gilbert Edgar, Westminster Hospital.
Davies, Arthur Gerald Capel, Guy's Hospital.
Harrison, Sydney George, Charing-cross Hospital.
Hill, Leonard Vincent, Firth College, Sheffield.
M'Ennery, Ambrose Richard, University College, Bristol.
Morris, Herbert Edward, Guy's Hospital.
Narramore, Edward Giles, School of Science and Technology, Liverpool.
Newton, Reginald Goldie, Oxford University.
Roberts, Stuart Kenyon, St. Bartholomew's Hospital.
Robinson, James Frederick, Birkbeck Institute.
Semmence, Ernest Edward, Royal College of Surgeons, Edinburgh.
Sloane, Hans Hill, St. Bartholomew's Hospital.

Elementary Anatomy:

Baker, Dodington George R. Sherston, University College, London.
Brinton, Arthur Greene, Mason College, Birmingham.
Carter, George Archibald, Royal College of Surgeons, Edinburgh.
Cathcart, George Elliott, St. Bartholomew's Hospital.
Dowman, Charles Darby Allen, St. Bartholomew's Hospital.
Everington, Francis Edgar, St. Bartholomew's Hospital.
Foster, Arthur Herbert, St. Mary's Hospital.
Graves, David Sydney, Guy's Hospital.
Green, Samuel Morris, University College, London.
Griffiths, William Layard, University College, London.
Hicks, Charles Edward, Guy's Hospital.
Jones, David Morgan, St. Mungo's and Anderson's College, Glasgow.
Lister-Kaye, Alan, Guy's Hospital and Mr. Cooke's School of Anatomy and Physiology.
Murdock, Horace Thomas Thorns, Yorkshire College, Leeds.
Perks, John, St Bartholomew's Hospital.
Prichard, John Llewellyn, University College, Liverpool.
Semmence, Ernest Edward, Royal College of Surgeons, Edinburgh.
Spiers, William Clark, St. Mary's Hospital.
Tordiffe, Arthur Murray Stewart, University College, Bristol.

SOCIETY OF APOTHECARIES OF LONDON.—The following candidates have passed in the under-mentioned subjects:—

Surgery.—Adams, E. G., Royal Free Hospital; Collinson, F. C., Leeds; Gough, E. M., Royal Free Hospital; Hedden, R., Guy's Hospital; Hughes, H., Liverpool; Lawrence, A. S., Middlesex Hospital; Silver, H. W., Charing-cross Hospital; Stamper, G. C., Guy's Hospital; Stewart, D. D., Liverpool; Tarbet, W. E., Sheffield; Thorne, M., Royal Free Hospital; and Whitmarsh, R. P. H., St. Thomas's Hospital.

Medicine, Forensic Medicine, and Midwifery.—Coker, A. P., Middlesex Hospital; Harmer, W. A., Aberdeen; Jones, R., St. Mary's Hospital; Langford, F. C., Charing-cross Hospital; Thorne, M., Royal Free Hospital; Welch, C., London Hospital; and Williams, H., Middlesex Hospital.

Medicine and Forensic Medicine.—Hort, E. C., Cambridge University and Guy's Hospital; and Merry, S. R., Charing-cross Hospital.

Medicine.—England, H., Sheffield; Graham, J. W. F., St. Bartholomew's Hospital.

Forensic Medicine and Midwifery.—Adams, E. G., Royal Free Hospital; Jones, H. G., St. Mary's Hospital; and Yorath, T. H. B., Guy's Hospital.

Forensic Medicine.—Ramsay, H. W., St. Mary's Hospital; and Wright, A. M. St. J., Madras.

Midwifery.—Hulbert, G. P. Y., Birmingham; Jackson, G. C., Cambridge University and St. Mary's Hospital; Stamper, G. C., Guy's Hospital; and Vale, C. S., Paris.

To Messrs. England, Graham, Hedden, Jones, H G., Jones, R., Lawrence, Ramsay, Stamper, Williams, and to Miss Gough and Miss Thorne was granted the diploma of the Society, entitling them to practise Medicine, Surgery, and Midwifery.

FOREIGN UNIVERSITY INTELLIGENCE. — *Gratz:* Dr. Alois Sachsalher has been recognised as *privat-docent* in Ophthalmology.—*Halle:* Dr. Eberth, Professor of Comparative Histology and Anatomy, has been appointed to the chair of Pathological Anatomy and General Pathology, in succession to Dr. Ackermann, retired; Dr. W. Roux of Innsbruck has been appointed to the chair vacated by Dr. Eberth.—*Kharkoff:* Dr. Barabasheff has been appointed Extraordinary Professor of Ophthalmology.—*Königsberg:* The title of Professor has been granted to Dr. G. Stetter, *privat-docent* in Surgery and Otology.—*Prague (Bohemian University):* Dr. J. V. Rohon has been appointed Extraordinary Professor of Histology.—*St. Petersburg:* Dr. Dogiel of Tomsk has been appointed Professor of Microscopical Anatomy.

THE DIFFUSION OF SMALL-POX.—The news as to small-pox prevalence continues to be of a favourable character, as the amount present in London, though small, is the largest contribution to the disease at the moment. During last week the number of patients suffering from small-pox in the metropolis removed to hospital was only 7, as against 21, 17, and 9 in the three weeks preceding; and the only death registered in the whole of the thirty-three towns of the Registrar-General's returns was in London, in the person of an unvaccinated infant of four months of age, which had been removed from the Bethnal Green sanitary area to the hospital ship "Atlas." The cases remaining in hospital at the close of the week have been steadily falling since the end of the fourth week of August, when they were 342, the number on Saturday last being only 119. These cases, however, cover a large area, as we learn of attacks as far apart as Shepherd's Bush in the west and Bethnal-green in the east; and on Monday of the present week there were three fresh cases in London. The Orsett board of guardians have been considerably exercised by the occurrence of cases of small-pox in the vicinity of the hospital ships at Long Reach, an outbreak at Purfleet and West Thurrock being placed to the credit of the small-pox ships in the river, ten of the eleven cases occurring within a mile of the ships, which the guardians desire to see placed lower down the river. In the four weeks ended Oct. 5th the small-pox cases notified in the whole of London totalled 108, an average of 27 per week, the average of the preceding like period having been 60, and 70 in the September four-weekly periods, so that the disease is showing much decline; and of the twenty-three sanitary areas (out of forty-three) invaded five only, and these all east and south, accounted for 69 of the 108 attacks, Bethnal Green being credited with 31 and Camberwell with 14. The news from the provinces shows that small-pox cases are but few. Essex alone in the districts adjacent to the Thames reports recent invasion. In Dublin the figures of the week ended Oct. 12th are much more favourable than in the week before. Only a single case was removed to hospital, and the remaining patients fell in number from 27 to 24, though one death was registered—namely, in an adult over forty years of age, and stated to have been vaccinated. Much discussion is going on now in the city on the vexed question of accommodation for the isolation of small-pox cases in the future, and the medical and sanitary world seems divided as to the danger or otherwise of isolating small-pox in the midst of the city population. We hope that wise counsels will prevail and secure the removal of all cases outside the range of populations of any magnitude. Some amount of friction has recently arisen at Bo'ness, in Linlithgowshire, on account of the removal to hospital by the sanitary inspector of the relatives of a small-pox patient notified in the borough, the medical officer and the local authority being at loggerheads on the point as to whether the inspector had any right to remove other than the immediate attendant on the patient. However, a compromise seems to have been arranged by the dismissal to their home of the quarantined relatives.

SERIOUS SEWER EXPLOSION.—A serious explosion took place at Farnham recently—where the Bishop of Winchester's castle is situated—in one of the public sewers. A town labourer had occasion to enter the man-hole where several sewers meet, and held a lighted candle in the mouth of one of them. Instantly there was an explosion, and the gas is said to have ignited and burnt in "variously coloured flames." A fellow workman went to the injured man's assistance, and medical aid was at once procured. The man was found to be suffering from severe burns and shock to the system. A doubt is expressed as to the nature of the gas which was confined, but it is well known that pent-up sewer gases contain hydro-carbons consisting chiefly of marsh gas, and therefore it is always a risky proceeding to examine a sewer with a naked light until the sewer has been ventilated. The fact of the accumulation of gases in the present instance speaks ill for the thorough ventilation of the drains.

DIPHTHERIA IN LONDON.—The condition of London in the matter of diphtheria prevalence is growing from bad to worse, and to-day the actual mortality from that disease in the metropolis is more than 40 per cent. in excess of the corrected average for the fortieth week of the last decennial period. The data for the four-weekly period ended Oct. 5th show that in that period as many as 1178 cases of diphtheria were notified in the metropolis, 41 of the 43 separate sanitary areas having suffered from the malady. Not only so, but in nine of those areas there were as many as 682 notifications, Greenwich having 114 to its credit, and 100 being placed to the credit of Camberwell. The weekly average was for London 295 attacks, as compared with only 202 in the preceding period of like length, and this shows a rise of very nearly 50 per cent. The registered deaths in this period to the 5th of the present month reached a total of 192, a weekly average of 48, or 16 per cent. of the notified cases; and the admissions to hospital 423, or only 36 per cent. of those cases. In the two weeks that have since elapsed the deaths have been respectively 56, or 17 above the corrected average, and last week the abnormal total of 76, or as many as 34 in excess of the average. In the fortnight we find the Registrar-General crediting sanitary areas as follows: to St. Pancras and Greenwich, each, 12 deaths; to Islington, Kensington, and Camberwell respectively 6 deaths; to Marylebone and Mile End Old Town, each, 5 deaths; and to Fulham, Shoreditch, and Battersea, respectively, 4 deaths. In the two weeks together only 2 of the 132 deaths occurred in persons aged over twenty years. Complaints are being made in several parts of the metropolis as to the difficulty found in securing the removal to hospital of many cases needing such removal, and the small percentage of removals to cases occurring seems to warrant the feeling that is abroad as to the necessity for a larger amount of isolation accommodation for fever patients. The admissions in the last two weeks have been 102 and 115; and the numbers of patients remaining under treatment on each of the last two Saturdays have been respectively 659 and 667. In the outer ring of the metropolis the deaths from diphtheria have been 27 in each of the last two weeks, and they have been located in the West Ham registration district to the number of 23; in Waltham Abbey district, 4; in Edmonton, 4; and 3 in Isleworth. So that the matter is not only of serious import to London county, but it is assuming serious proportions also in the extra-urban portions of the metropolis, even as far out as Waltham Abbey on the north. Indeed, the Edmonton union would appear to be passing through a diffused epidemic of limited extent at present, but none the less of a growing character.

Digitized by Google

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN.—The opening meeting of the new session of this society will be held on Monday, Nov. 4th, at 8 o'clock, when the President, Mr. David Hepburn, will deliver the inaugural address.

LITERARY INTELLIGENCE.—Mr. William F. Clay of Edinburgh will publish shortly an authorised English edition of the "Histo-pathology of the Diseases of the Skin," by Dr. Unna of Hamburg, translated by Dr. Norman Walker, Assistant Physician in Dermatology, the Royal Infirmary, Edinburgh. This new edition will be revised with additions by the author and will include forty-four additional illustrations specially drawn for this edition.

SUNDAY LECTURE SOCIETY.—The first of the series of lectures given by this society was delivered on Sunday afternoon last, Oct. 20th, in St. George's Hall, Langham-place, when Professor Sir Frederick Pollock, Bart., M.A., LL.D., lectured on "Tyndall as Worker and Teacher." Mr. C. W. Kimmins, M.A., D.Sc., will lecture on Sunday next, and the Rev. Stewart Headlam, B.A., Prince Kropotkin, Mr. Graham Wallas. M.A., Mr. Wyke Bayliss (President of the Royal Society of British Artists), and Mr. R. D. Roberts, M.A., D.Sc., on subsequent Sundays.

BRADFORD INFIRMARY EXTENSION.—The new buildings which have just been opened by the Hon. H. E. Butler, High Sheriff of Yorkshire, constitute a valuable addition to this infirmary. The estimated cost of the extension is £6000, but the new arrangements for heating and cooking will effect a saving of £200 a year. It is noteworthy that the institution, which, seventy years ago, began work with only 4 in-patients, treated in 1894 2086 in-patients. One desirable addition to the existing buildings is the observation ward, where suspected infectious cases will be isolated until the nature of the disease has been defined.

TORQUAY MEDICAL SOCIETY.—The annual meeting of this society was held at the Torbay Hospital on Oct. 2nd, and the following gentlemen were elected to take office during the current year. President: R. Pollard. Vice-President: T. Finch. Hon. Secretary: G. Young Eales (re-elected). Council: F. Thistle, F. Crowdy, Winwood Smith, and W. Powell. Hon. Librarian: A. Watson. Hon. Auditors: F. E. Cave and H. Cumming. A special meeting was held on Oct. 4th, Mr. R. Pollard, President, being in the chair, to hear an address by Mr. J. Hutchinson, F.R.C.S., F.R.S., on Heredity in Disease. The meeting was well attended, the audience including many members of the profession from Exeter, Plymouth, and the neighbouring towns to whom invitations had been sent. The annual dinner of the society, which was largely attended, was held the same evening at the Albert Hall, the president being in the chair.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward it to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week for publication in the next number.*

ALDOUS, G. F., L.R.C.P. Lond., M.R.C.S., has been re-appointed Medical Officer, Plymouth Public Dispensary.

BELBEN, F., M.B., B.C. Cantab., F.R.C.S., M., L.R.C.P. Lond., has been appointed Senior House Physician, St. Bartholomew's Hospital.

BENNETT, A., HUGHES M.D. Edin., F.R.C.P. Lond., has been appointed Consulting Physician to the Hospital for Epilepsy and Paralysis, Regent's-park.

BENNETT, W. E., F.R.C.S. Eng., has been appointed Senior House Surgeon to the Metropolitan Hospital.

BOTTOMLEY, F. C., M.B., B.C., B.A. Cantab., has been appointed Senior Resident Medical Officer to the Royal Free Hospital, Gray's-inn-road, London, vice W. H. Bowring.

BUCHAN, W. A., M.B., C.M. Edin., has been re-appointed Medical Officer, Plymouth Public Dispensary.

BURNETT, F. M., M.B. Lond., L.R.C.P., M.R.C.S., has been appointed Junior House Physician, St. Bartholomew's Hospital.

CALVERLEY, J. E. G., L.R.C.P. Lond., M.R.C.S., has been appointed Senior House Physician to the Metropolitan Hospital.

CHRISTOPHERSON, J. B., M.B., B.C. Cantab., has been appointed Senior House Physician, St. Bartholomew's Hospital.

COLLINGS, D. W., M.B. Lond., L.R.C.P., M.R.C.S., has been appointed Junior House Physician, St. Bartholomew's Hospital.

CORNISH, S., L.R.C.P. Lond., M.R.C.S., has been appointed Junior House Surgeon, St. Bartholomew's Hospital.

COSENS, WM. BURROUGH, L.R.C.P., Lond., M.R.C.S., has been appointed Honorary Surgeon to the Dorset County Hospital, vice G. A. George, resigned.

DRAKE, C. H., L.R.C.P. Lond., M.R.C.S., has been appointed Senior House Surgeon, St. Bartholomew's Hospital.

DUNN, W. E. N., L.R.C.P. Lond., M.R.C.S., has been appointed Assistant House Physician to the Metropolitan Hospital.

EMSON, A., L.R.C.P., L.R.C.S. Edin., has been appointed Medical Officer for the Workhouse of the Dorchester District of the Dorchester Union.

FOX, G. R., L.R.C.P. Lond., M.R.C.S., has been appointed Junior House Physician, St. Bartholomew's Hospital.

GILES, L., L.R.C.P. Lond., M.R.C.S., has been appointed Junior House Surgeon, St. Bartholomew's Hospital.

GUTHRIE, LEONARD GEO., M.D. Oxon., M.R.C.P. Lond., has been appointed to the charge of In-patients in addition to that of Out-patients at the Hospital for Epilepsy and Paralysis, Regent's-park.

HAMPTON, T., L.R.C.P. Lond., M.R.C.S., has been appointed Assistant House Surgeon to the Metropolitan Hospital.

HEDLEY, W. S., M.D. Edin., M.R.C.S. Eng., has been appointed Medical Officer in charge of the Electrical Department, London Hospital.

HEWER, C. M., L.R.C.P. Lond., M.R.C.S., has been appointed Junior House Surgeon, St. Bartholomew's Hospital.

HOGARTH, R. G., F.R.C.S. Eng., L.R.C.P. Lond., has been appointed Senior Resident Medical Officer to the General Hospital, Nottingham.

HOOD, N. L., M.B., B.C. Camb., has been appointed Assistant House Surgeon to the Sussex County Hospital.

JACKMAN, J. J. H., L.R.C.P., L.M., L.R.C.S. Irel., has been appointed Medical Officer to the Waterford Workhouse.

LAMPLOUGH, C., M.R.C.S., L.R.C.P. Lond., has been appointed resident Clinical Assistant to the St. Marylebone Infirmary, vice L. N. Gibbes, resigned.

LEE, W. E., M.B. Lond., L.R.C.P., M.R.C.S., has been appointed Senior House Physician, St. Bartholomew's Hospital.

LINDSAY, D. LAUDER, L.R.C.P. & S. Edin., L.F.P.S. Glasg., has been appointed House Physician to the Glasgow Royal Infirmary.

MARTIN, RICHARD STANLEY, L.R.C.P., L.R.C.S. Edin, L.F.P. & S. Glasg., has been appointed Medical Officer and Public Vaccinator for the Lever District of the Bolton Union, vice J. Martin, deceased.

MICHELL, R., M.B., B.C., F.R.C.S. Eng., has been appointed Junior House Physician, St. Bartholomew's Hospital.

MURPHY, J. K., L.R.C.P. Lond., M.R.C.S., has been appointed Senior House Physician, St. Bartholomew's Hospital.

PHILLIPS, L. C. P., M.B., B.C. Cantab., L.R.C.P. Lond., M.R.C.S., has been appointed Senior House Surgeon, St. Bartholomew's Hospital.

POWERS, C. H., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer for the Gosforth Sanitary District of the Whitehaven Union.

POOLE, S., M.B., M.S. Edin., has been appointed Medical Officer for the second Wolverhampton Sanitary District of the Wolverhampton Union.

POYNDER, F. C., M.B., B.Ch. Oxon., L.R.C.P. Lond., M.R.C.S., has been appointed Junior House Physician, St. Bartholomew's Hospital.

RENDLE, A. C., M.B., B.C. Camb., L.R.C.P. Lond., M.R.C.S., has been appointed Physicians' Assistant, Plymouth Public Dispensary.

ROGERS, K., M.B. Lond., L.R.C.P., M.R.C.S., has been appointed Senior House Physician, St. Bartholomew's Hospital.

ROUE, W. BARRETT, M.D., M.S., has been appointed Consulting Physician to the Bristol Hospital for Sick Children and Women.

THOMAS, T. W., M.R.C.S., has been appointed Medical Officer for the Caerphilly Sanitary District of the Pontypridd Union.

THOMPSON, GEO. R., has been appointed Analyst for the Borough of Neath.

WATT, J. L., M.B., M.S. Aberd., has been appointed Medical Officer for the second division of the third district of the St. German's Union.

Notes, Short Comments, and Answers to Correspondents.

EDITORIAL NOTICE.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side only of the paper.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

FEES AND THE LOCUM-TENENT.

A CORRESPONDENT writes:—"A few weeks ago I had occasion, when acting as locum-tenent in Scotland, to sign a lunacy certificate. To whom does the fee go? Am I entitled to it, or does it go to the principal? There is a difference of opinion amongst the members of the profession in regard to the above." To this we have to say that all fees made or earned by a locum-tenent are obviously due to the practitioner whose place he is holding, in the absence of any special contract to the contrary. Occasionally it happens that a fee represents some unusual duty or service, when there is much to be said for its being divided between the principal and his assistant, but this is a matter of grace on the part of the principal.

Dr. Augustus H. Bampton is thanked for his interesting communication with regard to the procuring of immunity from malarial fever. The treatment suggested, however, is, in the present state of our knowledge, a little visionary, and we do not think that its promulgation would serve any practical purpose.

H. B. would be glad to hear of any recent book on Cottage Hospitals and Convalescent Homes and the publisher's name.

"PERSISTENT HICCOUGH AND SNEEZING: A SUGGESTION WANTED."

To the Editors of THE LANCET.

SIRS,—If there be no lesion of the cerebrum the case is most likely of the rheumatic gout nature. Salicin in thirty-grain doses three times a day will effect a cure in four days or less, if my surmise be correct. If the case should be due to organic nervous system derangement producing an erythematous condition of the nasal, pharyngeal, and gastric mucous tracts of an intermittent nature, small doses of arsenic, nux vomica, and iron three times a day, with milk and lime-water night and morning, will be the remedy. I have known a case of a gentleman affected with sneezing which suddenly attacked him after intervals of a few weeks, and lasted day and night continually. I have known a case where hiccough, sneezing, and laryngeal asthma were periodic visitants. Arsenic and tonics relieved the first; salicin cured the second. I am, Sirs, yours truly,

Kingstown, Oct. 21st, 1895. JOHN ROCHE, M.D.

MEDICAL WORK AND ITS REMUNERATION IN WALES.

THE *Western Mail* says that a movement is on foot at Llanelly to secure an increase in the fees paid to the medical officers of the various works. At present the payment is only 9*d.* per month to cover medical attendance for each workman and his family. In other towns the rate is 1*s.* Some have already conceded the very reasonable demand, but at Morewood's Works it is intimated that if the medical attendant is not satisfied his resignation will be accepted. We trust that the workmen here will reconsider their resolution and the inadequacy of the pay of the medical man. If they do not, and drive the present holder to resignation, it will be discreditable to any medical man to take the vacated post. Nine shillings a year for medical attendance on a man and his family who are in receipt of good Welsh wages is not just.

Dr. H. Harley.—The Sickness and Accident Assurance Association, Ltd., of 64, Moorgate-street, E.C., offers insurance of the kind indicated by its title to professional men; and the Medical Sickness, Annuity, and Life Assurance Society, of 33, Chancery-lane, E.C., covers the sickness risk. But we are not able to decide upon the comparative merits or competing claims of these two societies.

Mr. John Newton.—We never give medical advice or recommend treatment, and regret that we can be of no service. Our advertisement columns contain the addresses of many institutions that might serve our correspondent's purpose, and his medical attendant can help him to a choice between them.

A. Z.—There does not seem to be any publication containing the desired information. Particulars concerning the meteorological qualities of any specified locality can always be obtained, but such a comprehensive work as our correspondent seeks has yet to be written.

H. S.—The "Laboratory Guide," by A. H. Church, M.A., F.R.S. (Gurney and Jackson, 1, Paternoster-row).

Joseph S. P. has neglected to supply us with his full name and address.

"A FEMALE MEMBER OF THE ARMY MEDICAL STAFF."

To the Editors of THE LANCET.

SIRS,—As the correspondence on Dr. James Barry's strange history makes little or no mention of her military career, may I be allowed to supplement my letter in THE LANCET of last week with a few particulars?

Reference to Hart's Army List for the year 1865 will show that "James Barry" stands at the head of the list of Inspectors-General of Hospitals. In July of that year the *Times* one day announced the death of Dr. Barry, and the next day it was officially reported to the Horse Guards that the Doctor was a woman. She was buried at Kensal Green, and over her grave was erected a tablet with the simple inscription: "James Barry. Born ? Died 1865." These facts, the proceedings of the inquest, and the registry of her death should be still available as verification of the Doctor's sex. The dates of her several commissions in the army will be found as follows; but it is very remarkable that the grades of "Surgeon," "Assistant Inspector," and "Brevet Deputy Inspector" of Hospitals were passed over in her case:—Hospital Assistant, July 5th, 1813; Assistant Surgeon, Dec. 7th, 1815; Surgeon-Major, Nov. 22nd, 1827; Deputy Inspector of Hospitals, May 16th, 1851; Inspector General of Hospitals, Dec. 7th, 1858; retired on half-pay, July 19th, 1859; Died, July, 1865. In "Fifty Years of my Life," by the late Earl of Albemarle, at page 96, vol. ii., will be found some interesting comments on Dr. Barry's services and death. He says: "A mystery attached to Barry's whole professional career, which extended over more than half a century. While at the Cape he fought a duel and was considered to be of a most quarrelsome disposition. He was frequently guilty of flagrant breaches of discipline, and on more than one occasion was sent home under arrest; but somehow or other his offences were always condoned at headquarters. ..... It is singular that neither the landlady of *her* lodging nor the black servant who had lived with her for years had the slightest suspicion of her sex. The late Mrs. Ward, daughter of Colonel Tidy (Military Secretary, Jamaica, 1856, and at the Horse Guards, 1855), from whom I had these particulars, told me further that she believed the Doctor to have been the legitimate granddaughter of a Scotch earl whose name I do not now give, as I am unable to substantiate the correctness of my friend's surmise, and that the *soi-disant* James Barry adopted the medical profession from attachment to an army surgeon who has not been many years dead." In a letter to me from Surgeon-General McKinnon he states that he found Dr. Barry to be "a pleasant and agreeable man. He neither cursed nor swore, but behaved himself like a gentleman. I have heard many reports about him, and the most of them were false, the people making them being obviously interested parties. I never heard of his ever being an operator of any kind, nor do I think he ever had any opportunity of showing his skill in that line." On the other hand, Surgeon-General Longmore, writing to me from Netley in 1882, says: "I acted as P.M.O. at Trinidad for nearly a year shortly after Dr. Barry vacated the post. I also saw her in the Crimea, when staying with Lord Raglan on a visit." And in an appreciative comment on my treatment of the case in the character of *Dr. Fitzjames* in my novel, "A Modern Sphinx," he adds: "Some years ago a French writer in a history of 'Le Médecin Militaire' remarked: 'Le fait en lui-même ne laisse aucun doute; et cependant je doute fort que Miss Braddon elle-

Digitized by Google

même oserait jamais faire de cette personne l'héroine d'un de ces romans.' *You* have accomplished what the writer evidently thought no one dare do."

I could tell several amusing stories of Dr. Barry's "mistaken identity," as, for instance, that of the adjutant of a regiment in Jamaica requesting the Doctor to discontinue visiting his wife just at the hour he had to be on parade or in the orderly room. But most of these anecdotes I have interwoven into my novel, "A Modern Sphinx," or its reproduction, "Madeline's Mystery," either of which volumes may no doubt be found in some of the numerous libraries of the country.

I am, Sirs, yours faithfully,

Savage Club, Oct. 21st, 1895. H. ROGERS, Lieutenant-Colonel.

To the Editors of THE LANCET.

SIRS,—I have great pleasure in sending you my recollections of "James Barry," the lady surgeon referred to in your columns.

It was in the year 1844, I think, that I was sent from Barbadoes to Trinidad to sit on a general court-martial, which was exciting great interest in the islands at that time. On the assembling of the court an individual appeared as spectator who at once attracted my attention. He was in the full dress of an army surgeon, but had all the appearance of being a woman. On making inquiries I was told that the individual was Dr. Barry, the principal medical officer of the district. The impression and general belief were that he was a hermaphrodite, and as such he escaped much comment or observation in places where everyone was used to him. But I was under the belief that there had never existed a true human hermaphrodite; so that I was convinced James Barry was a woman about sixty years of age, and being much interested in him I cultivated his acquaintance and we became very friendly. He frequently asked me to visit him, and I endeavoured to draw out his antecedents, but found him very reticent. The only thing that I discovered was that Lord Fitzroy Somerset (afterwards Lord Raglan) was a friend of his, from which I inferred that it was to him Barry owed his high position. He was a vegetarian and drank only water.

Some years ago I read of his death, and that his sex had been discovered, as well as traces of his having borne a child.

I am, Sirs, yours faithfully,

Oct. 17th, 1895. CAPTAIN.

*** We have received the above letter from an intimate acquaintance of the late Dr. James Barry through Mr. Henry Taylor, F.R.C.S., of Quarry-street, Guildford, who, remembering that he had heard a gentleman speak of having made this curious person's friendship, kindly wrote in our behalf for particulars. Mr. Taylor also refers those of our readers who are interested in the case of James Barry to "a capital story of a Spanish nun, in the seventeenth or eighteenth century, who enlisted in the army and served with much credit in the West Indies and Spanish Main, written by M. de Hérédia, the French poet, and purporting to be a true history." Several correspondents also refer us to the account of James Barry given in Taylor's "Principles and Practice of Medical Jurisprudence," edited by Dr. Thomas Stevenson, fourth edition, vol. ii., p. 290. This chapter contains allusions to the Chevalier D'Eon and several other of the more notorious impersonators of sex.—ED. L.

WHAT IS LIFE?

To the Editors of THE LANCET.

SIRS,—As this subject is discussed separately in the current issue of THE LANCET by no fewer than three great authorities—Professor Beale, Professor Rindfleisch, and Sir James Crichton Browne—it is evidently of more present interest than I had supposed. To my understanding, however, the problem is about as hopeful as the process described in one of Æsop's fables—"Viper gnawing file"! Many years since I read both Büchner and Beale, but of course with no decisive result, though I considered that the former had the better case. In later years I have read Huxley, and agree with him that there is no prospect—as I have already stated—of the question being settled, and that, therefore, of the three alternatives—materialism, animism, and agnosticism—the only rational choice is, unsatisfactory as it may be, to candidly, if not cordially, accept the last, provisionally at any rate. If that is so, are not the scientific gentlemen in question rather too dogmatic against what Professor Rindfleisch calls "the tyranny of materialism"? I cannot but think that animism, whether old or new, is more presumptive and difficult of acceptance than materialism, and that Huxley's agnosticism bids fair to hold the field for long enough against all positivism on the subject. So far the thing is an inscrutible mystery, and it is, therefore, foolish to conjecture about it.

I am, Sirs, yours faithfully,

Oct. 21st, 1895. ONLY A MEDICO.

THE MORPHIA HABIT.

To the Editors of THE LANCET.

SIRS,—Would any of your readers who have had experience in the treatment of the above do a great kindness by naming the best work on this subject, and stating whether or not there is any drug or means of mitigating the suffering during the treatment? Is the morphia habit less likely to be acquired by one who takes it for *bond-fide* suffering than by one who has either been carelessly slow in giving it up after recovery or who indulges in it for mere pleasure? I write on behalf of a great sufferer who is compelled, and will be for some time, to use hypodermic injections.—I am, Sirs, yours faithfully,

Oct. 21st., 1895. VIGILANS.

THE EFFECT OF HEAT.

THE *American Meteorological Journal* for October contains a paper by Mr. B. S. Pague on "Sensible Temperature, or the Effect of Heat on the Body in California." Over the great valleys of the Sacramento and San Joaquin, and over that large area of the State removed from the immediate coast and south of the Tehachapi Mountains, maximum temperatures of from 106° to 118° are experienced during the summer months, and as high as 122° have been recorded in Death Valley in July. The temperatures noted are from Weather Bureau records, and show the temperature of the air, the thermometer being in the shade in a standard thermometer shelter. Mr. Pague states that the reason these temperatures do not kill is that, while the degree of heat noted is that which is actually recorded, that which is known as the sensible temperature is about 40° less, dependent upon the amount of moisture in the air, and it is this sensible temperature which affects life. By sensible temperature is meant that which is felt at the surface of the skin where the skin is exposed, as on the face or hands. This temperature is obtained from the usual form of wet-bulb thermometer. The highest temperatures on record at San Francisco during the months from June to September, inclusive, average 95°, while the sensible temperatures on the same days average 65°. At Yuma the average highest is 116°, and the average sensible temperature at the time of highest air temperature is 75°. This shows that, while high temperatures prevail at periods of the year, the temperature which the body is required to endure is about 35° less than the air temperature recorded, and this difference is due to the amount of moisture in the air. If the air were as moist as is found in the region of the Great Lakes and along the Atlantic seaboard, and the temperature as high as it now is at times, the effect of the heat would be to kill by what is called sunstroke the greater number of the population, to destroy vegetation, and to desolate the country that now produces as much and as great a variety as does the most favoured section of the globe.

Mr. K. P. Popat.—Our Students' Number contains full information as to the examining boards of the United Kingdom and their requirements. It would be impossible to give our correspondent this sort of information about America, where every State can make its own arrangements.

H. A. C.—We do not identify the author of the testimonial to Rudd's remedy. The name and description do not exactly correspond to any in the Medical Register. Can our correspondent give us exact particulars of name, address, &c.?

M.R.C.S., L.S.D.—The situation our correspondent describes to us is decidedly galling, but he will understand that we cannot express an opinion upon it unless both sides of the question are made clear to us.

WANTED, AN EXPLANATION OR A SUGGESTION.

To the Editors of THE LANCET.

SIRS,—Would any of your readers give me an opinion on the following case? A child aged eight years was revaccinated a year ago. Four vesicles resulted, one of them imperfect. A growth subsequently appeared in each of the cicatrices, and at the present time the condition is as follows. There are three hard, freely movable masses of pink-coloured, smooth, shiny tissue of almost cartilaginous feeling. The masses are of almost the same size, oval, and about three-quarters by half an inch in their diameters, raised above the surface of the surrounding skin by about one-eighth of an inch. The outlines are regular, but the three masses are joined in their long diameters by thin portions of the same tissue about one-eighth of an inch long and one-sixteenth of an inch wide. A very much smaller mass occupies the site of the cicatrix of the abortive vesicle. The masses are quite painless, but as the patient is a little girl the unsightliness of the arm has to be considered. A brother of the child was revaccinated whilst away from home at school at about the same time, and he has developed precisely the same condition. The family history is very good and the children otherwise extremely healthy. What is the probable nature and cause of the growths, and are they likely to be of a keloid nature, when removal would not be advisable? What would be the most appropriate treatment to adopt?

I am, Sirs, yours truly,

Oct. 21st, 1895. CICATRIX.

A Subscriber.—No such work as our correspondent requires is known to us. The time has hardly arrived for such a summary of knowledge necessarily recent, but he will find scattered through our columns information embracing all the different points.

THE Liebig's Extract of Meat Co., of 9, not 6, Fenchurch-avenue, E.C., as printed in an analytical report in THE LANCET of Oct. 12th, point out that their new preparation is called *Peptonum Carnis*, and not "Extractum Carnis."

ERRATUM. — On page 1004 the words "75 millimetres," "50 millimetres," "33 and 36 millimetres," ought to have been respectively 75 μ, 50 μ, 33 and 36 μ. 75 μ are equal to 0·075 millimetre, and the other figures should be read in that proportion.

An Address
ON
SOME OF THE LIMITATIONS OF MEDICINE.

Delivered at the Opening Meeting of the Session of the Medico-Chirurgical Society of Exeter, on Friday, Oct. 18th, 1895,

BY JAMES F. GOODHART, M.D. ABERD., F.R.C.P. LOND.,
PHYSICIAN TO GUY'S HOSPITAL.

GENTLEMEN,—In Mr. Leslie Stephen's life of his brother, Sir James Fitzjames Stephen, there occurs this passage with reference to the choosing a profession by his distinguished lawyer brother: "He therefore begins in the most prosaic fashion by an attempt to estimate the pecuniary and social advantages of the different courses open to him. These are in reality the Church and the Bar, although, by way of exhibiting the openness of his mind, he adds a more perfunctory discussion of the merits of the medical profession. Upon this his uncle Henry Venn had made a sufficient comment. 'There is a providential obstacle,' he said, 'to your becoming a doctor, you have not humbug enough.'" Now that was, of course, some forty years ago, and there are those who may think that the medical man of to-day is not the man of that long gone time. Nor is he. It would, indeed, be a sad day for all of us if, with all our immense additions to knowledge, the world had no better medical men now. But I should not be disposed to let even our ancestral worthies rest under any such offensive imputation. They acted in their day quite as much up to their lights as we do now. But I take it that, in passing it on, the writer of the memoir from which I have quoted has in some measure made the present day responsible for a similar impression, and I am afraid it is true that a good section of the general public—and even, I fear, it must be confessed, not always the least discriminating—has floating about in its mind, and sometimes lets escape in veiled speech, that a medical practitioner must be more or less of a humbug. It is very interesting in looking over our weekly *Punch* to see how sometimes the artist misses true humour by being too absolutely real. This is so with the "Old Millionaire" of Oct. 12th. What could be more pathetic than that very old man with his "no expectations"? But it is no caricature. The same may be said of the medical man of good bedside manner and small acquirements of a few years ago. It, too, was painfully real, with a double edge, for it cut both at the public and at the supply which in some small measure its demand has created. It is a good illustration of my text. I have thought it, therefore, not inappropriate to our meeting to-day to discuss one or two of the conditions under which we are obliged to practise that seem to me to conduce to such an erroneous notion. And it seems to me that the explanation is to be found first and chiefly in the uncertainties of medicine; next, perhaps, in the impossibilities—the forlorn hopes—we are so constantly being called upon to deal with and to lead; and, thirdly, I would add, in some degree with our manner of dealing with such limitations as these under which we labour. Now the uncertainties of our work are so many and so manifest that it might, indeed, seem quite unnecessary to mention them; but I shall tax your patience by a few of them, and they shall be some of the commonest, though perhaps not too well known for all that.

Let us take the matter of diagnosis first. How great is often the practical difficulty of coming to a conclusion upon the real state of a particular person's lungs. There are those who may, perhaps, think that the existence, say, of cavities in the lungs can be determined with ease—and I do not say that it is not so for many cavities; but we all know that a large cavity may exist in the lung without giving any signs of its presence, provided that it be surrounded by healthy lung tissue or that the bronchus by which it communicates its physical signs be blocked. It may not, perhaps, have occurred to all of you to observe, on the other hand, how a very small cavity, provided that it be near the surface and surrounded by condensed lung, may give all the physical signs of a large cavity, a point of the greatest importance now that surgical procedures have added so largely to the resources at our disposal for the treatment of diseases of the viscera. And I take it that in this fact is to be found the explanation of another fact, also an illustration of my present contention—viz., that it is by no means uncommon to obtain the physical signs of a cavity in cases where the lung is only consolidated in acute pneumonia. Take another case. It is practically impossible in many cases to speak positively as to the existence of early phthisis. Many a patient has been said to have had phthisis, and, perhaps, has spent winters abroad in consequence, who has never had anything of that sort the matter with him; while many another on the brink of a galloping tuberculosis has been pronounced sound by equally competent authorities. Then take the heart; and how uncertain often are the signs of grave muscular weakness, so that a really experienced man shall say one day that there is nothing the matter and the next day sudden death takes place. I may even take up a more extreme position and say how uncertain often are the evidences of enlargement of the heart. We are all hearing now of what the general public is pleased to call the new treatment of heart disease, the treatment by mechanical exercises and so forth. I cannot now discuss the value of it. It has its value undoubtedly in selected cases; but I want to say that any support it may derive from the varying amount of præcordial dulness before and after the exercises is of a very unreliable description. We all know that in the post-mortem room the largest hearts are often found unsuspected, and that even under very competent hands a large heart sometimes becomes, under the rigid presentation of the dead-house, a very large heart indeed. Emphysematous lungs are a great hindrance to the detection of large hearts, and for the same reason—the greater expansion of the lung under the exercise—no observation upon the præcordial dulness before and after exercise is of much value. I may note two other points concerned with the same difficulty. I allude to the doubt that there often is about estimates of the amount of fluid in the pleura. One can, perhaps, generally say that there is fluid in the chest, but often and often one cannot get any idea from the physical signs how much there really is. The diagnosis of pericardial effusion labours under the same disabilities. To be certain of even considerable effusion in this sac is often a matter of the greatest difficulty, not to say impossibility; and I think I may say that I have had a rather exceptional experience of such cases. Here, again, the post-mortem room tells that many a pericardial effusion has descended to that department unrecognised, and, on the other hand, that sometimes an effusion suspected, or even diagnosed, is not found. I have seen a pericardial sac cut down upon as being full of fluid, after the most careful examination, only to be found dry. In the abdomen, again, appendicular colic seems to have added a new terror to diagnosis by necessitating a still further differentiation of colics. It was bad enough sometimes to have to decide between nephritic and hepatic colic, between neuralgia of the kidney—if there be such a thing—and simple colic. And, by-the-bye, in passing, is there such a thing as a simple colic agony, for by such a term only can I explain my meaning? Is one ever justified in attributing to simple spasmodic intestinal pain any attack so severe as to induce vomiting? Are not these the signs of calculus, or peritonitis, or twists, or something dreadful? I think that unbearable pain from simple intestinal muscular action is rare, although it may well seem somewhat inconsistent to allow its existence for such an insignificant little canal as the appendix cæci and to doubt it in the case of the bowels proper. But, perhaps, it is the very insignificance of the appendix that constitutes its sting. Even the worm will turn. That a pure appendicular colic—that is, colic due to disease in the appendix cæci in association with retained mucus—will occur without the existence of any inflammation of the peritoneum I have indisputable proof, but no doubt I ought to ask pardon of the surgical section of my audience for putting forward so elementary an assertion. But for us poor physicians I would again insist that its existence has added a new terror to life for the medical man as well as his patient. And if one turns from the uncertainties caused in diagnosis by what might, indeed, seem straight sailing conditions, what are we to say of those countless questions that obtrude themselves upon our attention when we have to decide between the many ill-adjusted balances of physiological relation—between such states of ill-health and their differences as are caused, say, by one organ failing to do its proper share of work and where other organs are called upon

Digitized by Google

to do the more, of which perhaps the hypothesis of renal inadequacy may serve to clear my meaning? Such hidden meanings must result in perplexed purpose, and perplexed purpose is the opportunity of chance.

It is still worse when we come to grapple with the uncertainties, not of diagnosis, but of treatment; because here in still greater force comes out the individuality of man. What does this not mean when you come to champion health and pit yourself against his many maladies. This living machine (we call it a machine, and perhaps it will be in the future) is in truth a great coöperation where each department differs greatly, one factory from another, in intuitive ease of working, in capacity for work, as well as in methods of working. We are for ever assuming—perhaps we are obliged to assume—that our bases of operation are constant; whereas the very opposite is the fact, and much of our uncertainty comes from the patient and not from his disease. There are those who go through life without a day's illness, and there are those who seem to "catch," as it is called, every thing that is going. There are those whose every cut turns to a sore—though I daresay the surgeon turns aside to whisper, "Yes, if not properly treated"—and there are others whose perhaps serious wound never looks back in the process of repair. There are those whose stomachs think no evil of assafœtida, and others to whom the most delicately prepared pill of a simple drug acts as a poison. There are those again to whom climate seems to be the main obstacle to at any rate pleasurable existence, and others who can go anywhere, do anything, and never turn a hair. Yet all these varied existences have to be treated, and treated for diseases that have the same names in the one and in the other, and treated by the same drugs, more or less, that are allocated to each disease. To prescribe for a headache may be an easy thing, albeit not always very successful; but to prescribe for John's headache, and Thomas's headache, are different things. "There are at least six personalities distinctly to be recognised as taking part in a dialogue between John and Thomas," says the Autocrat of the Breakfast Table. You know them: "The real John, known only to his Maker," who is not his physician unfortunately. It is, indeed, too sadly true for applied physic that the medical man's patient is never the real John, or John's John, but often very unlike either. We, indeed, know nothing of the details that produce individuality—one might almost fear that we never can know, forged as we are in the past and moulded by the present, constantly adapting ourselves to changing circumstances. To attempt to control disease as modified by such unstable conditions might well seem hopeless—an attempt to reorganise and reform a complex system that is the growth of years: a task meet, indeed, for the reformer who is blind to disaster even in the wreck of revolution, but not for the thoughtful mind, not for the balanced judgment, not for us. Happily, things are not so uncertain as they might seem, and day by day they become a little less so, but for the present, and for long, it must still be that we know much less than we do not know. And this ought to be made as clear to the mind untrained to medicine as to us.

Of the impossibilities of medicine—and although it will have been apparent that medicine has been used to include all branches I will yet specially here note the fact—I will take only one, the greatest of all: the attempt to cure the incurable. That is what we are constantly being asked to do. I have known a man come to town and visit five or six surgeons, one after the other, in a morning to get rid, if it were possible, of the terrible incubus of a diagnosis of cancer of the tongue. An intense love of life is in the immense majority of the human species a part of the fact of the possession of it. Only a very painful disease or an exhaustion of such nervous centres as appreciate the happiness of living can crush it out. The medical man possesses it himself equally with his patient. Is he to crush it out? He could not if he would. Death is inconceivable to those who still climb upwards on the hill of life. The reality of death comes only as the physical fact comes—slowly. No man not past his work can know of a readiness to die. Rather is it that he can see no reason save the awkward one of fact why men do not live on for ever. Thus beaten—sadly beaten, as he too often is—the medical man rises from the ashes of defeat untaught, unteachable: indomitable still, instinct as is the sick one with the potentialities of life. And it is this one great living instinct of hope that underlies all the difficulties of medicine and—God forgive them—that leads the undiscerning to think that the medical man must be a humbug. Knowing more than they, we can readily allow that it is this great unconquerable attribute of life that does indeed seem to place us sometimes in equivocal circumstances. Let us look a little into this. In the first place, and because of it, medical men are believed systematically to suppress the truth; and in the second place—this is a criticism that comes from within us—in our eagerness to do our best for our patients and to cure or ameliorate the results of disease we no doubt sometimes err—for my own part I shall say often err—by the over-treatment of disease or of symptoms.

And, first, as to the systematic disguise of the truth. The common complaint of the man in the street is generally this (I borrow from a letter addressed not long ago to one of the medical papers by "a patient"): "If," says this person, "a patient is content to accept his doctor's prescription without inquiring too closely into his opinion of the nature of the case, I do not think it is incumbent on the doctor to reveal in all cases his suspicions of grave danger. But where a patient is clamouring to know what is the matter with him, it is too often the doctor's habit to return not only evasive but misleading replies, and I am strongly of opinion that the suspense and anxiety which result from this practice are frequently more injurious than the knowledge of the truth would be." "If," the writer says further on in his letter, "the impression that doctors habitually deceive their patients for their patients' good were once removed I am certain that the general esteem in which doctors are held would be greatly increased." This is, of course, only an opinion, and I cannot think that it is worth much because the writer talks of a rule of the profession not to take the patient into confidence in serious cases. I know of no such rule. Each case is decided on its own merits, and if such separate decisions in the gross have resulted in a practice of this kind it must be because medical men have seen reasons for concluding that it is on the whole the one most conducive to the welfare of the majority of minds. I do not claim for ourselves that we are better than any other body of men, but we are not worse, and if, for the sake of argument, we do habitually tell lies, the very disinterestedness of our damnation may well be considered as very strong evidence of the necessity that we think to be laid upon us. Medical men, unfortunately, know more of the natural man than does the patient quoted. They know that there are three classes of patients, if not more. There are those who really want to know all that we can tell them—the very truth. I put this group first in deference to the view of the "patient" I am combating, but it is, in my opinion, a very small group indeed. These generally succeed in making it quite clear that they really are in earnest in their request, and, in my experience, the absolute naked truth is told them. Then there are those who, having asked for the truth, did not really know their own minds; they only wanted favourable truth, and when it turns out unfavourable they seek an opportunity to go away from Dr. A—— to Dr. B——, because, say they, Dr. A—— is so abrupt, or so desponding or depressing, or always takes the worst view of his cases. In another still larger group of cases the question is never faced at all. They may have grave fears about the gravity of their malady and they unconsciously minimise their symptoms. They may brood over and fear the worst, but they never ask for an opinion, they never even mention their suspicions or fears themselves; these leak out perhaps by the sigh of relief that results from a cheery verdict or from the furtive aside of an accompanying friend. I venture, therefore, to state, as the result of deliberate and experienced conviction, that just as it is those who have little the matter with them who go about in fear of death—not those whose days are really numbered—so those who are not stricken with mortal illness are clamorous to know the truth, and those who are mortally wounded in the battle of life seldom seem to have any desire to know. The desire that they should know comes usually from the bystanders and concerns itself with the great question, "What next?" That "Won't you tell him?" when the physician gives an adverse verdict implies that most beautiful and most poetic, but most unreal, idea that man passes over the confines of Time and enters the Land of the Future with all his faculties vivid and intense in transit. But is it so?

"And may there be no moaning of the bar
When I put out to sea"

is very beautiful, but it is not applicable to the mass of

Digitized by Google

mankind. Death seldom comes to man till his intellectual faculties are incapable of appreciating that passage of the bar. Thus there is nothing terrible to the dying in death itself. The veil between two worlds is but a cloud, and one passes through it imperceptibly.

If we except, then, such as have not arranged their affairs where it is of real importance for those who are to be left behind that this should be done, and those who, wanting to know everything, are granted their wish, I shall admit that for the large majority of the remainder, not that the truth is systematically disguised, but that the worst points in a case are kept in the background, and that the more promising ones are made the most of. I am prepared to justify this practice as not only the most humane, but as the best thing to do in the interest of the prolongation of the life at stake. And first of all, What is truth? As I write this I have come from the bedside of an old lady aged eighty-four years, stricken with acute pneumonia at the apex of one lung. She said as I was leaving her, "I know you won't deceive me; if I am going to die you will tell me the truth." Was I to say, would it have been right to say, "At your great age you are nearly certain to die"? That would have been the truth, and no more than the truth, for such a case, and would have been exactly what I thought. But truth can be brutal as well as kind. Was it not more humane to tell her that she was very ill but going on exceptionally well, which was the truth disguised or presented with "tact" or however you like to express it? Who can doubt that the right thing to do was to leave the patient with the life-sustaining hope, a hope that I certainly shared, although hardly daring to expect to see it realised? Well, then, how often in a single experience does it happen to a man to be able to say, while his patient is in a condition to be able to take advantage of it, "you have only got so long to live." In this very case I have mentioned the patient has recovered from her pneumonia, although the ultimate issue at such an age must still be very doubtful. Over and over again a patient has been given up by his medical attendants only to return to healthy life, and not uncommonly to make a life-long laughing-stock of those who have condemned him. Years ago, when resident house physician at Guy's Hospital, I arranged with the sisters in the medical wards that I should be called to every case that seemed to be dying. I wanted, apart from my duties, to obtain also some actual knowledge of facts that foretell immediate dissolution. It was a painful and depressing ordeal, and having gone through it I cannot say I am better informed now than I was before. I still find it as impossible as ever it was to get behind that impassable barrier of Providence,—The day and the hour knoweth no man.

I have chosen this, the most vital, question upon which to defend our freedom of judgment as to how we shall present our opinions to individual patients, because this is the one where our wisdom is most commonly called in question. But there are numberless other circumstances in which, if we would do the best we can for those who consult us, we cannot always say exactly what we think. We may, for example, think that a certain individual drinks too much. It is seldom advisable to blurt out, "You drink." At least, if one did it is more than probable that all chance of influencing the patient for good would be sacrificed, and that much obloquy and even personal loss would result to the medical man, for such people as this will talk and are not usually particular about strict veracity. So what is called "tact" is necessary, and tact is a vehicle to disguise the real taste of the truth. Thus careful inquiries about the daily diet of the patient are gradually worked off the meats on to the drinks of the ailing one, and the amount of claret taken daily. Of course, he or she never takes anything stronger. Thus is obtained an opening upon which to discourse upon the hostility of alcohol to some constitutions, and to this one in very particular. There are any number of times when one is equally unable to put things as bluntly as might for some reasons be desirable. For instance, to tell a lady that she is hysterical is equivalent to asking her to attend the practice of your most hated rival. Also, if you want to keep your patients you must not say they are nervous. This I know from experience. You may say they are highly strung. I conclude, therefore, that to tell brutal truths to patients is on several accounts mostly impossible, and I fail to see why we are dubbed untruthful on account of such inability.

In the matter of the over-treatment of disease, although it comes from the best of motives, perhaps hardly such intelligible reasons can be given for its occurrence. But in the first place I must say what I mean by over-treatment, and I will do this by appealing to current thought. No doubt you have all seen a correspondence initiated by an address given at the British Medical Association by Sir William Priestley upon Over-operating in Gynæcology. Sir William Priestley has been much taken to task by some of our surgical *confrères* from what, it seems to me, is a very narrow point of view, in that it has been made a class question of the physician, who is jealous at the success of a surgical coöperator. But I venture to say that the question must be considered from a much wider standpoint. It is not for anyone of us to play the part of the saucepan calling the kettle black, and I do not propose to confine my criticisms to any one branch of practice. Looked at from this broader aspect by the dispassionate watcher of the tide of progress, there is surely much that is wise, nothing that is not true, so far as I can see, in Sir William Priestley's address. And I will take medicine first and point my argument by illustrations. There came into my room the other day two brothers in the prime of life. They looked healthy, and they were healthy, but they complained of indigestion. You all know how much or how little that may mean. They both had the same tale to tell. They were full of gout, so their medical adviser said, and they had been taking the waters to drive it out. I went into their habits and their history with the greatest care, fully determined to find out anything that there might be that was treatable; and I am sure that if anyone could look at those two young men, apart from the bias engendered by the continual treatment of disease, he would say, as I do, that they are specimens of perfect health. This seems to me a good illustration of over-treatment, and is an example which, *mutatis mutandis*, will apply to a good many cases that we all meet with—men and women who will have medicine although they do not want any so far as their bodily condition is concerned. Let me give one more common case—that of the lady who, being wealthy, has had plenty of time to pay undue attention to her varied sensations. Say that there is something rather crocky about her family history, and this has made her unduly anxious about her lungs. She therefore consults many medical men, and perhaps one or another suggests the possibility of the presence of tubercle. She is seldom long without a medical man afterwards; she goes here and there and everywhere in search of health, and it is doubtful whether she has ever been tuberculous at all. And as this leads me to the subject of tuberculosis it will do as well as any other disease to illustrate the point under consideration.

I cannot but think that there is great danger of our letting the facts run away with us as regards the exact importance of the bacillary origin of tuberculosis. Once phthisis is shown to be infective, it is by many at once assumed that infection is infection, always the same, and to be dealt with always in the same manner. I have elsewhere treated of this matter,[1] but as the present occasion affords me the opportunity, as it were, of crying aloud upon the housetop I will say again that if anything is sure in the history of tuberculosis this is that the infecting agent is *not* a virulent one and is in many respects quite peculiar in its methods of invasion. Years ago, in making experiments upon rabbits and guinea-pigs upon the production of artificial tuberculosis, I found, as Wilson Fox had found before me, that the nature of the injury to the animal was comparatively immaterial. Tuberculosis was induced whether the primary lesion was the insertion of tubercle itself or the introduction of bits of cloth, of setons, and so on. Any chronic irritant appeared equal to producing it, and the disease was explained in those days as a matter of lymphatic hyperplasia, of infection from cell to cell, one cell imparting its morbid activity to another—a form of activity that has been banished from the pathology of the present day, but one which, I take the liberty of thinking, will some day become rehabilitated in the esteem of pathologists, when the bacterial boom shall have receded to its just proportions. But other observers followed, of whom one of the first, if not the first, was Dr. Dawson Williams, who showed that if the experiments were carefully conducted, and all the instruments carefully sterilised, no tuberculosis resulted save where tubercle had first been inoculated. It has been assumed from experiments such as these that the primary essential is, therefore, the introduction of the tubercle bacillus, and the other changes are the result of its introduction. But I have always

[1] Medical Magazine, 1894.

Digitized by Google

thought that a rider to this is also possible; for in the first place it might well seem a little strange that out of a very large number of experiments so many non-tuberculous lesions should yet become inoculated with such regularity, whereas there was an important difference in the mode of operating in that the conditions resulting were just those to reduce the local inflammation to its lowest possible degree. Therefore, it may have been that in avoiding local inflammation a large part of the risk of the introduction of tubercle was also avoided. There are many facts in the history of tuberculosis that show that this is really so. A case in point readily comes to my mind. In the spring of the present year I was asked to see a young man who, in previous good health, had about the end of an influenza epidemic come home one evening, had a rigor, and from that time forward was feverish. After about ten days a friend of mine who was attending him asked me to see him because the fever was continuing, and no cause could be discovered. Just at that time a small patch of pneumonia began to show itself at the lower part of the right lung, and I said that no doubt the man had had influenza, and out of it had come a slowly developing pneumonia, as is not uncommon, and that now things would go on aright. There was, I think, something against the patient's family history, and I was therefore pushed as regards the possibility of the disease being tuberculous. But I said, "No." The disease did not begin like a case of tubercle; the initial rigors were much more like a pneumonia; the apices of the lungs were perfectly sound, and he would do all right. The case went on as one expected for some days; the whole of the right base solidified, and when we met again two or three weeks later the whole of the lower lobe was absolutely solid, the apex remaining quite healthy. But now time was getting on and the temperature was regularly up to about 102° F. every night, and again I had to defend my position that the case was not one of phthisis. I still refused to admit that the case was tuberculous. We now had the sputum examined, and on two occasions it was found free from bacilli, and I still stuck to my guns. But time ran on still further, and after six or eight weeks the lung showed no sign of resolving, or the temperature of abating; and now the sputum, when examined, showed a few bacilli, and later the bacilli became fairly numerous. What was I to say now? Many would say it has been an unusual case of phthisis, beginning at the base of the lung. It may be so; but for my own part I think the proper explanation of such a case is such as I have contended for in the tuberculosis produced in rabbits by setons and so forth, and that the pneumonia has let in the tuberculous germs, and that in this way the case becomes one of secondary tuberculosis. I give this case because it is an unusual and an interesting one, but there are any number of parallel cases; and I take it that the practice of the future, not perhaps the near future, will be a rebound to the teaching of a bygone day, not a struggle with countless hosts of invisible enemies, a struggle that might well seem hopeless did we stop to think about it, but, with increasing powers of securing health, a recognition of the fact that by keeping people healthy these microbic armies lose their terrors.

This is not to say that we need not avail ourselves of the precautions inculcated by our present-day knowledge of bacteriology. That would, indeed, be folly. It is to say that our precautions are to follow our knowledge and not to run in advance of it. And this is a distinction very necessary in the matter of tuberculosis. What are the facts as regards phthisis? There is no mistaking the drift of opinion. We are beginning to regard this disease as we do any other of the infectious diseases, totally different as most of them are in natural history. We are now taught that phthisis can be caught, and isolation is being preached as the right thing if it could be accomplished. Notification also has the same half-suppressed advocacy, and after it, or with it, comes the disinfection of houses in which the tuberculous have lived. I saw a case of phthisis the other day, and he left me to go and stay with his sister. Within a post or two this lady wrote to me to know what I thought of infection, because she had young children and she was herself delicate. I am often getting such letters.

Let us ask ourselves what we really know as to the value of disinfecting houses that have been inhabited by the tuberculous. I know nothing, but I dreamed not long ago that from some coign of 'vantage I beheld a stronghold of bacilli grown big and visible in the illusions of the night assaulted by the sanitary inspector with his sulphur and his lime, and as the fumes arose these bloated midges giggled to themselves at the pleasure they derived from the unusual perfume. But by-and-bye Messrs. Soap and Water came upon the scene, the windows were opened and the winds of heaven let in, and then it was that they turned tail and fled. Harassing precautions are all very well when we know that they will accomplish the end in view; but in the case of the tubercular bacillus we have no such knowledge, and for the present we had much better content ourselves with insisting upon absolute cleanliness and plenty of ventilation. We shall be in accord with, but not in advance of, our knowledge, and we shall have a much better chance of having our orders attended to. I should think there is nothing more sure in medicine than that the tubercle bacillus has special attributes, that it is not easily caught, and that it is successfully dealt with by common-sense precautions without turning society upside down. One other point with reference to this same disease. Do you not think we overdo the extradition of phthisis? It may be, and is, all very well and advisable that people who have plenty of money, and who can obtain every luxury, should travel for their health. They can carry home with them in a measure, and at the end of the voyage, as at the beginning, they have only to please themselves. But I am seeing every few days almost some poor clerk or shopman, or governess may be, who has been advised to go abroad for a weak chest. "And what," I ask, "are you going to do when you get there?" "Oh! look out for some work," is the reply. "Do you know anything of the country?" "No." "Have you any friends who can help you?" "No." "You are going by yourself?" "Yes." Thus they would go to a strange land without knowing a soul, and in search of clerical work, where workers of that sort who are strong are at a discount, and mostly are spending the small sum of capital saved or raised because they or their friends want to do the very best for them. And too often it is the very worst for them.

Aneurysm of the arch of the aorta is another malady that is, I think, too often over-treated. But it is a disease so desperate that one may be excused for making somewhat frantic efforts to save the life of the patient. I would, however, insist that we do not know the natural duration of any aneurysm. We know that they are practically incurable and that many last a long time—three, four, five, or even seven years—if under favouring circumstances. It is my belief that a very rigorous treatment in the way of dieting and prolonged rest in bed is a dangerous one unless directed with great judgment. It eases some symptoms, and in a solitary case now and again it has been said to cure. But I doubt if the good results are any set-off to the harm that is done by its routine application. The best that can be done, in my opinion, for an aneurysm of the arch of the aorta at present is to look upon it as incurable by any means; to, therefore, allow gentle exercise, with occasional rests in bed if pain be severe or there be signs of rapid increase of the aneurysm; an ample diet of good blood-making food, including fats, which the late Dr. Wooldridge showed by experiments to have some power in increasing the coagulable quality of the blood; reducing as far as practicable, without destroying the comfort of the patient, the amount of fluid taken in the twenty-four hours, and giving such drugs as are suitable to the case. Anything further than this—and cases are often treated much more rigorously—is what I should call over-treatment.

With some trepidation, too, I am inclined to say that a very different disease is made more of than its importance deserves, and that is ringworm. I never now attempt to treat it; I send it on to the dermatologist. I cannot cure it, and very often he cannot. And sooner or later it is taken out of his hands, and either left alone or treated by the herbalist with ink or Condy's fluid, who then, having made to himself friends of the mammon of unrighteousness as far as he deems judicious, calls it cured, and thenceforth the child is let loose again upon society. I often wonder when I hear of a child with ringworm of a year's, or perhaps two years', standing, and, of course, kept out of school and away from his companions all that time, what would have happened to his associates equivalent to the harm that has accrued to the child and his attendants from the treatment that he has undergone. Honestly I should very much like to see the parable of the tares and the wheat applied to this disease under scientific observation. To start with, no doubt, the sheep and the goats—I mean myself and the dermatologist; no, I beg pardon, the dermatologist and I—should differ as to the prospects of the

Digitized by Google

harvest, *I* not expecting in the end to have much of the tares to deal with, *he* not much of a field of wheat. Anyhow, I am quite sure of this—that we should hear much less about ringworm—whether for the good or evil of the community I will not attempt to decide—if mothers had not got it into their heads, quite erroneously, that it is a dirty disease. Not long ago I was seeing a baby that had scurvy rickets, and the father was bemoaning the hardness of his luck, that, whereas he had always considered his family as a particularly clean one, one child had recently had ringworm and now another had got scurvy.

This is a very fair confession for me as a physician. Very shortly let me turn my attentions to surgery, and first I will say that I have often of late years asked myself the question whether we do not make too much of lateral curvature of the spine. Did anyone ever yet see a slight curve go on into a very bad one? It seems a rational assumption enough that it is so. But are we sure that it is so. It is mostly a disease of girls, and mothers quickly get into a panic if a shoulder is supposed to be growing out, and then we advise what is now the proper treatment, a prolonged course of the most irksome exercises. Now do not let anyone who is interested in this or any other subject I have treated think I am wishing to speak *ex cathedrâ*. I come before you in all these questions I have raised an honest doubter wanting to know if such ideas as have occurred to me have not also presented themselves to you. I see something of these cases, as do you, under different circumstances and at other times, odd times, than those at which the specialist sees them. And I incline to think that slight spinal curvatures, which form the staple of the successes in treatment, are a distinct class of cases from the bad cases. If not, then I should conclude that an incurable, I will not say an irremediable, condition is very quickly reached—at least, very many seem to be told they should have come before, and that they are bad cases and can only be prevented now from getting worse. Then surely there are some lateral curvatures that advance in spite of the best treatment. All things considered, then, I would venture to ask whether we should content ourselves with the groove in which we are now running—that the slightest lateral curve discovered, the sufferer must at once go in for a long course of specially adapted exercises. No doubt this plan is both more physiological and more rational than the now mostly discarded one of instruments and supports, but it does not seem to me that the results of even this method of treatment are quite so satisfactory as its advocates would have us believe. And I am not quite satisfied that we do not make too much fuss over these cases, and that the early ones would do just as well by turning them out to grass and insisting upon healthy, enjoyable exercise in healthy surroundings, combined with plenty of rest. Flatfoot is another condition the exact importance of which it is difficult to appraise. There are hundreds of people going about with flat feet and not in the least inconvenienced thereby. It is only in the small proportion of these cases that there are pain and so forth. So that it would seem that the trouble is more in the individual than in the shape of the foot; and I incline to think that we sometimes make too much of the foot and too little of the individual who owns it.

I will only mention one more affection, and that the disease of late years called adenoid vegetations of the naso-pharynx. Again, do not let anyone misunderstand me—I am not belittling the enormous amount of good that has come to humanity by the recent methods of dealing with these growths. I should think ear disease and tuberculosis starting in the neck and stunted development have been reduced enormously by the surgical treatment of these growths. But I do think, from what I have seen, that they are tending to become the red rag to the bull. I have in the course of the last few years seen children where the removal of these growths has been advised and where there was not one single symptom of their presence. They were there, but they caused no symptoms. He would do a good piece of work, in my opinion, who would make observations upon the proportion of children in our large towns who have this condition. I am inclined to think three-fourths of all would be no great over-statement of the number affected. At any rate, they exist in a large number of children without any symptoms, and I cannot think that it is wise to interfere in the absence either of deafness, or of enlargement of glands, or of a contracting chest, and so on. A lady came to me one day some time ago about her daughter. It appeared that not long before her small son had had adenoids, and as it was necessary to remove these the medical men thought they had better circumcise him at the same time, and no doubt it was a wise and proper proceeding. But the way it came to the mother's vision was that he had been "trimmed up all round," as she expressed it, and she came to me to protect her daughter from a similar fate. And that recalls to mind that the other day an American lady came to me with a child, and when she was seated she opened the ball by asking, "Have you a disease that is called appendicitis over here?" I replied that I had heard of it. "Well," she said, "where I come from they don't think anything of you unless you have had at least two cases in the family." So that it appears that over the water also our surgical brothers suffer, as we do, from a most unreasonable prejudice against the use of the knife! It is my belief, then, that in all branches of our professional work excess of zeal in treatment does occur. But, inasmuch as it is the necessary consequence of that enthusiasm without which no such responsible work could make any real progress, I do not think it can be altogether avoided. But let each of us see to this.

And here I must stop. It is not my purpose to point the moral to what I have said—I do not, indeed, know that it can be pointed; for, however it has been treated, my subject opens up large questions and great issues both to the medical man and his patient. And it is in this dual relationship that the difficulties occur; for mostly it is that our difficulties and errors of action are not those of our own making—they are forced upon us by those to whose service we have committed ourselves. But I think that we should all probably agree that we should find ourselves less often in troublesome corners if we more often kept the upper hand in dealing with our patients. The patient leads us in all manner of directions where we ought to lead him. For instance, he seems to me to have come to look upon a medical man as the repository of all knowledge, so that anyone who happens to say "I don't know" is looked upon as an ignoramus. Our patients need to be more constantly taught that doubt is no evidence of ignorance. One of the good things said by the late Sir William Gull is thus reported. He was attending a scion of nobility with one or two other medical celebrities of the time, and allowing their doubts to appear his lordship said: "Well, gentlemen, *you* don't seem to know what is the matter with the patient; is there anyone else that can give us more information?" "Yes, my lord," said Sir William Gull, with his usual readiness, "plenty if they are ignorant enough." I am constantly told that I must give some name to a doubtful case. I object altogether to give names to diseases that have not declared themselves, and I think that the friends of the sick, and the sick themselves where possible, ought to be educated on all possible occasions up to the understanding that there are diseases that no drugs can cure; that there are diseases that get well without drugs; that there constantly crop up sets of symptoms that admit of several different interpretations, and that hesitation and doubt may be as sure a measure of knowledge as decision. I think, too, that the time has come when, unintelligent as the layman seems to be in matters pertaining to his health, a resolute effort should be made to induce people to think for themselves. Can the practice of medicine be in a really sound state when we have to tell Mr. Dick, Mrs. Tom, and even, as I have several times known, adolescent Harry, that they may eat mutton but never touch beef, that they must not touch potatoes, and that they may have a warm bath at night, but not a cold one in the morning? There are few things less hopeful of the future of medicine than that at this the end of the nineteenth century it still seems necessary to treat grown up men and women as if they were children, and, what is worse, to find that dispensing leading strings finds much acceptance. You all know very well how the natural man curls up when someone comes into your room with the introduction, "I want you, please, to tell me what I may eat and drink." How your outward man at once congeals into a smug sitting-for-your-portrait sort of mien; and your inner man attempts to see things honestly as the patient sees them and to reason out the possibility that for this individuality dangers hitherto undreamed of may really lurk in every article of daily food, except perhaps toast and whisky, which seem very seldom to disagree. You have some of you no doubt felt, as I have often done after interviews of this kind, that an inward soreness has been left behind, a half

Digitized by Google

questioning doubt whether in thus accepting such childlike faith one has not put back the promise of the future. For if the public will ask our advice about details upon which, if they only thought for a moment, they would see that they themselves must of necessity be far better judges than ever a stranger to their habits can be, what hope is there that they will ever be able to consider with you those weightier matters of the law, those subtle aberrations of function, those insidious early changes that constitute the beginnings of disease? Yet unless they are in some measure able to follow these with their medical advisers how can they possess their souls in patience—how can they ever be far off the patent medicine or the quack? And from these, in that future we shall not see, but which will yet surely come, may medicine be emancipated.

An Address
ON
THE SURGERY OF TO-DAY AS COMPARED WITH THAT OF TWENTY-FIVE YEARS AGO:
ILLUSTRATED BY THE WORK IN THE GENERAL INFIRMARY AT LEEDS.

Delivered before the Leeds and West Riding Medico-Chirurgical Society on Oct. 18th, 1895,

BY A. W. MAYO ROBSON, F.R.C.S.ENG.,

PRESIDENT OF THE SOCIETY; SENIOR SURGEON, LEEDS GENERAL INFIRMARY; AND PROFESSOR OF SURGERY IN THE VICTORIA UNIVERSITY.

GENTLEMEN,—I must first thank you for the honour you have conferred on me by electing me to the most distinguished position of President of this important society, which, both on account of its members as well as from the value of its papers and discussions, not only holds a premier position among the provincial but is second only in general interest to two or three of the chief metropolitan societies. It is customary for your President to deliver an address at the opening of the session, and as my predecessor in this chair reviewed the work of this society up to last year I have had to look around for another subject. I thought that a comparison of the surgical work of to-day in the General Infirmary at Leeds, the institution in which we regularly meet, as compared with that of twenty-five years ago, might prove of sufficient interest, as it would tend to show what a reformation—or shall I term it a revolution?—in surgical thought as well as in the science and art of surgery has taken place in the past quarter of a century. To those of my hearers who, like myself, have passed through this most critical period of the history of surgery, it is most evident that the changes in these twenty-five years are simply marvellous, and if we compare the report of the Leeds Infirmary for 1870 with that for the year 1894, issued in 1895, we can see not only that the mortality all round has lessened, but that in certain operations, had not a change come, their performance would have had to remain a matter of history, since the mortality was so high as to render them almost unjustifiable. The number of operations has increased remarkably. Whereas there were in 1870 271 general and 198 ophthalmic operations, making a total of 469, in 1894 there were 1527 general, 1200 minor, 1171 ophthalmic, and 141 gynæcological operations, making a total of 5039; and whereas the all-round mortality in 1870 was 6·6, in 1894, although the magnitude of the operations performed was in many cases infinitely greater, it had fallen to the notably low percentage of 1·2; so that if the number of operations had been equal in the two years, and the mortality had remained the same, there would have been 332 deaths in 1894 instead of 60. An analysis of the hospital registers for the years named affords some interesting and startling facts; for instance, in the 1894 report the following operations are recorded which have no place in the report of 1870: radical cure of hernia, of which no less than 53 cases are given; osteotomy, 69 cases; removal of vermiform appendix for recurrent appendicitis; cholecystotomy and other operations on the gall-bladder; enterectomy, prostatectomy, gastrotomy, pyloroplasty, hysterectomy, nephrectomy, laminectomy, laryngectomy, bone-grafting, nerve-grafting, and others, all of which are now well-established, useful, and successful operative measures. In the same way a reference to the registers shows that some surgical diseases, unfortunately too common in 1870, are now happily rare, and in some instances have no place in the record of 1894. I refer to hospital gangrene, phagedæna, pyæmia, erysipelas, septicæmia, secondary hæmorrhage, and such-like surgical misfortunes. No better example can be given than that of tetanus; for twenty-five years ago it was not very unusual to see this fatal disease follow even slight operations, yet during the last fifteen years I have not seen a single post-operative case, all instances that have come under observation having occurred after neglected wounds received outside the hospital.

Perhaps in no class of cases has greater progress to be recorded than in abdominal diseases, which formerly were for the most part treated expectantly in the medical wards. For instance, in 1870 and 1871, under the heading "Abdominal Section" no case is recorded; in other words, the peritoneal cavity was only opened for ovariotomy and for strangulated hernia; whereas in the two years 1893 and 1894 573 patients had abdominal section performed in this hospital, the all-round mortality—including malignant cases, strangulation of gut, cases of acute intestinal obstruction, internal gangrene, suppurative peritonitis, &c.—showing a mortality of 12·2, or a saving of life in 87·8 per cent. The statistics of ovariotomy in this hospital twenty-five years ago were so bad that tapping was frequently resorted to in order to defer the major operation, and even in 1875 12 patients were thus treated, only 7 having been submitted to the radical operation. Out of these 7, 5 died, yielding a mortality of 71·3 per cent. On the other hand, in the years 1893 and 1894 ovariotomy was performed 132 times with 123 recoveries, giving a mortality of 6·8 per cent., and seeing that this includes malignant cases as well as patients extremely ill in other ways, the mortality is one of which no hospital need feel ashamed. For it must be borne in mind that statistics are in no way considered, and if an operation offers any chance of giving relief it is resorted to. Only a few years ago it was the custom to treat these cases in single wards and to have two special nurses for each, but as the work increased this was found to be impracticable, it being impossible either to provide sufficient small wards or nurses, and it soon became manifest that the patients treated in the general wards recovered equally well. Hence, isolation was given up, and it is now the custom to operate on these cases in the theatre and to remove them to the general wards, just as is done with other surgical cases.

Compound fractures afford a bright example of progress in treatment, for instead of amputating where the large joints are opened or where the bones are extensively smashed and the soft parts lacerated, and instead of the majority of cases having to go through a tedious process of healing by granulation, possibly with the complication of abscess and secondary hæmorrhage, and after many weeks or months recovering with stiffened joints and impaired functions, at the present time, although joints may be opened and the bones severely smashed, so long as the circulation can be carried on amputation scarcely enters into the question, and the limb is put up, after purification of the wound, with every prospect that the case will pursue the ordinary course of recovery like a simple fracture. Thus there is not only effected a great saving of life and a much more rapid restoration of function, but a marked diminution in the time spent in hospital. In this way, as well as in the treatment of joint diseases, surgery has become much more conservative and amputation is now only looked on as a *pis aller*, and almost as a sign of failure; though, if amputation has to be done, the mortality of to-day compares very favourably with that of twenty-five years ago, for, including all the major amputations, the mortality of 1870 was 20·8 and of 1875 25·60, whereas in 1894 it was only 11 per cent. This conservative tendency is exemplified by the care exercised to attain perfection in the repair of injured tissues, whether accidental or operative; for instance, it used to be considered satisfactory to bring all the tissues in an abdominal wound together by sutures piercing the whole thickness of the abdominal wall, the result not infrequently being a yielding of the cicatrix and the development of a ventral hernia; but by bringing peritoneum to peritoneum, muscle to muscle, aponeurosis

Digitized by Google

to aponeurosis, and skin to skin, the integrity of the parts is restored and permanent weakness avoided. In no class of wounds does this great care show to more advantage than in injuries of the forearm and hands, where suture of tendons and nerves is thought of as much importance as union of skin; even if there be a deficiency of nerve or tendon modern surgery is equal to the occasion, since grafting of both can be successfully effected. The aiming at cure, or as nearly as possible at complete restitution, rather than simply at relief, is exemplified in the performance of ovariotomy in place of paracentesis, of excision of joints in place of amputation, of erasion or simply removal of disease instead of excision, of enucleation of thyroid tumours instead of thyroidectomy, and of prostatectomy in place of drainage or frequent catheterism. The operation for strangulated hernia illustrates not only the greater success 12·5 per cent. mortality in 1894—against 33·3 in 1870 and 60·6 in 1874—but the difference in aim of the modern surgeon, for in 1870 the saving of life was, as a rule, simply considered, and the patient on recovery was left more crippled than ever, since the hernial aperture was as a rule larger, whereas at present the radical cure is considered an essential part of the operation. In consequence of the almost absolute safety of operative interference at an early stage of strangulation, and the almost certain cure of the hernia, very little time is wasted on taxis, and operation is urged as being a blessing, though in disguise. Even in those very terrible cases where, through ignorance or neglect, the intestine becomes gangrenous, unless the patient is too ill to bear more than a mere incision, instead of establishing an artificial anus a cure is aimed at by excision of the gangrenous loop and restoration of continuity by means of simple suture or by means of some apparatus such as the decalcified bone bobbin or the metal button, the closing of the neck of the sac so as to form a radical cure completing the operation.

In the treatment of certain impacted fractures such as Colles's fracture of the wrist at any age, or impacted fracture of the cervix femoris in a healthy young or middle-aged man, union is certain if the case be left to nature, but I take it that any surgeon would feel dissatisfied with his work if he simply rested content with securing union without restitution. In the same way, in transverse fracture of the patella bony union and complete restitution, which were once rare events, are now definitely aimed at either by extra- or intra-articular suture. The tendency of modern surgery is to be thorough, this being well exemplified in the treatment of malignant disease; for instance, in cancer of the breast no surgeon would now consider his work satisfactory who simply removed the tumour without amputating the whole of the breast as well as clearing out the axilla, just as in cancer of the cervix uteri he will perform supra-vaginal amputation or complete hysterectomy no matter how early the disease be discovered. The benefit of this thoroughness is shown in the lengthened respite or in some cases in the complete cure. That the thorough operation in these two classes of cases which have served me for examples is safe is shown by the 1894 statistics, for, of the 36 amputations of the breast and of the 9 hysterectomies for cancer, all recovered. I might have mentioned two other examples of the thorough removal of malignant disease in laryngectomy for malignant disease of the larynx and proctectomy for cancer of the rectum, both of them being comparatively new and successful operative procedures.

In the days when any simple operation wound might be followed by serious complications the advice necessarily given, where the question was one of mere disability or of deformity, was, "Be content with the ills you have rather than those you know not of"; but now that wound complications with due precautions can be discounted our sphere of usefulness is widely extended, and our advice as to operation is well exemplified in the report for 1894, where it will be found that besides the 53 radical cures of non-strangulated hernia for the removal of disability no less than 64 osteotomies were performed for the rectification of crooked legs or thighs, to say nothing of the numerous plastic operations performed simply for their æsthetic effect. I remember the time when healing by granulation was considered quite satisfactory, and occasionally the surgeon would be gratified by obtaining primary union; now not to obtain healing by first intention in clean operation wounds is considered discreditable to modern surgery and to the institution in which it occurs. Then, not only daily, but several times a day, the dressings had to be changed, whereas at the present time one dressing is applied at the operation, and as a rule is not changed for a week or longer or until the wound is quite healed. I find that so late as 1880 over five tons of linseed were supplied to the infirmary to be used as poultices for wounds, whereas in 1894 the amount was so small that it is not entered in the list of stores, and at the present time I think the student would have to make his acquaintance with this commodity outside the surgical wards. On the other hand, the amount of cotton-wool supplied last year was over five tons, it being chiefly used in the manufacture of the antiseptic dressings salufer or salicylic wool. Although an improvement in results was steadily being brought about by increased cleanliness and by improved sanitary arrangements it was not until the introduction of the antiseptic system by the father of modern surgery, Sir Joseph Lister, that surgery emerged from the darkness and uncertainty which had surrounded it for ages to the scientific accuracy and greater certainty of the present time. The truth of this is proved, if proofs were needed, in the facts I have mentioned, culled from our own hospital records, which are open to all. The change was not simply a gradual evolution, but a well-marked revolution, not depending so much on merely manipulative dexterity (for our hospital twenty-five years ago could boast of the greatest surgical skill) as on an increased knowledge of the causes of surgical disaster and how to avoid them. While on this subject it would be base ingratitude to pass on without an expression of profound sorrow for the loss sustained by science and by mankind in the person of M. Pasteur, that genius who, from the discovery of the causes of aberration in the processes of fermentation in alcoholic beverages, extended his theories so as to enlarge the whole range of pathological thought by showing the intimate relation between fermentation and contagious disease, an extension of this study leading, as we all know, to the practice of antiseptic surgery. Since the Listerian reformation in surgery evolution has been taking place all along the line both in surgery and among surgeons themselves.

The time has passed for the surgeon to be obstetrician, general practitioner, physician, and surgeon blended in one; the true surgeon must give his life to his work, and must be an artist as well as a scientist, conversant at the same time with physiology and pathology as well as with anatomy and bacteriology; he can no longer shirk the work of diagnosis and accept the dictum of the physician as to when he should operate or decline to operate, but he must be able to use his brains as well as his hands in order to attain to an ideal. Nowhere is more judgment required than in those difficult cases, most frequently abdominal, where, even with the co-operation of his medical *confrère*, only an approximate diagnosis can be arrived at, and where the awaiting of developments which would clear up the mystery means the loss of life. In such cases exploratory operations, because of their safety, are becoming more and more frequent; in the 1894 report 10 such are given, all of which recovered; but this does not represent the whole of the truth, for in many cases the designation is afterwards affixed to the bed paper though the operation began as an exploratory procedure. In other words, whereas formerly diagnosis was considered essential before operative interference, now operation at times precedes diagnosis. The increasing tendency to "operate when in doubt" will do much to lessen the number of cases to which "too late" has yet to be applied. The surgeon never had such responsibility resting on his shoulders as at the present time, for it will no longer serve him to blame the supernatural for his own oversights or auto-infection for germs introduced by himself or his assistants. Knowing what we do of the causes of wound complications, and how without that knowledge it was practically impossible to avoid them, it should excite in the mind of the surgeon of to-day the most lively admiration of the able men who brought our art to the state in which it was in the period preceding the antiseptic era. Although they were disquieted by failures which they believed to be beyond control they had the courage to rise above their disasters and in many cases to score successes which the modern surgeon might consider impossible under such adverse circumstances. In accepting the responsibility of operative work the surgeon has to place himself to a certain extent in the hands of those assisting him, and as the strength of a chain is tested by its weakest link, so his success may be marred by the ignorance or the carelessness of another. In hospital work and in

Digitized by Google

surgical clinics this difficulty does not arise, as the surgeon can carefully select his own assistants. In a school so large as the medical department of the Yorkshire College, and with the large amount of clinical material at our disposal for the purposes of teaching, the student has every possible advantage to make himself proficient, and while dresserships are available for all, to those who are diligent and who choose to avail themselves of their opportunities the resident appointments at the infirmary are open, so that the want of skilled assistants is never felt in hospital practice, though in private work at the homes of the patients the difficulty is at times not a little embarrassing. Hence I think it will be found that at the present day, given the skilful and careful surgeon, his success will be greatest in the following order—(1) at the surgical clinics where he is personally responsible for the assistants, nurses, and general *entourage;* (2) in his hospital practice, where the responsibility is divided and where his assistants are frequently changing; and (3) in the private homes of patients where the surroundings are often ill-adapted to the purpose and where the responsibility is still further divided.

Twenty-five years ago I think it would have been found that the greatest success followed the surgeon's efforts in the homes of his patients and the least in his hospital wards, because of the prevalence of wound complications in the latter and the greater purity of the air and of the surroundings in the former. Surgery has, however, not yet attained its goal, and much good work remains to be done. The members of this great society, as they have in the past, will doubtless in the future contribute their share; not only in surgical but in medical science in its various branches has the society done useful work and signalled progress, as we hope and believe it will continue to do in the future.

GLEANINGS FROM SURGICAL PRACTICE.

BY THOMAS BRYANT, M.Ch. F.R.C.S. ENG. & IREL.,
CONSULTING SURGEON TO GUY'S HOSPITAL; PAST PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND, &C.

I.

I PROPOSE in the following papers to collect and hand down to those who may be interested in past surgical work some of the lessons which can be imparted to others out of the many that I have learnt during a somewhat extensive surgical experience, and in so doing to record brief notes of such rare and exceptional cases as I now, after a process of free elimination, find retained in my notebooks; for during the past year, when occupied in looking over my records of hospital and private cases, I speedily realised the conclusion that, whilst the notes *en masse* would, when I have passed over to the majority, be useless to anyone, some of them, and particularly those of private cases, might be misemployed. Under these circumstances I have submitted all my notes to a process of sifting, and after throwing away what may be called ordinary examples of disease or injury I have preserved only such as appear to be typical, rare, or exceptional, and I must add that the notes of most of these have been condensed down to what could be recorded upon a half-sheet of note-paper. From these condensed notes of sifted cases I shall illustrate this and all future papers.

I.—INJURIES OF THE ABDOMEN WITHOUT EXTERNAL WOUNDS.

For the first of the series I have selected those which refer to the subject of injuries of the abdomen without external wounds, since it can hardly be open to a question that the diagnosis and treatment of this class of cases are, as a rule, very puzzling to most practitioners, not only on account of the difficulty which is always experienced in arriving at an accurate diagnosis of the nature of the injury which may have been sustained, but because there are no cases which call for more prompt or decided measures when the diagnosis of the case is sufficiently clear to allow of such being carried out; indeed, it is on account of this uncertainty of diagnosis that so many cases of abdominal injury are too often allowed to drift until the hour for active beneficial interference has passed, and the surgeon learns too late in any individual case from its necropsy that by the help of his art repair might have been rendered possible and recovery probable. How to make the diagnosis of these cases more certain will form an important part of this paper.

In estimating the nature of the injury in any individual example care should always be taken to learn from the eye-witnesses of the accident every detail connected with its occurrence which can be obtained, particularly as to the nature of the force which has been applied, and the direction of its application with reference to the position of the patient at the time of injury. The condition of the patient's clothes should also be well looked to, for by such a scrutiny a conclusion may be deduced as to the exact seat of impact or direction of the injuring force; indeed, these points taken together much help the surgeon to form some conclusion respecting the nature of the case he has to treat after its due investigation. It must always be kept in mind that a case, which may at first sight appear serious from having been the result of the application of a powerful force, may in its progress prove to have been of the nature of a trivial injury; whilst, on the other hand, a case that may have been regarded as one of a trivial nature from having been brought about by a slight force may be followed by the gravest consequences. Thus I have seen the two side wheels of a four-wheeled waggonette holding two adults pass over the abdomen of a boy aged six when on his back without doing more harm than that produced by fright; and I have known the blow from a stone the size of a walnut thrown from afar, after striking a girl aged seven on her abdomen, produce a rupture of the small intestine which caused death. And yet the fact to which I have drawn attention and the cases I have quoted to illustrate it must not mislead us, for it is essential that all surgeons should acknowledge that, as a rule, the greater the force applied to the abdominal contents the greater probably will be the injury the viscera and vessels have sustained. Thus the passage of a wheel over the abdomen, as a diffused, dragging, and crushing force, is most likely to be followed by a bruising or laceration of parts; whereas the blow of a stone, a fall upon a stone or small blunt object, a kick, or like injury, where the force of impact has been quite local, is more prone to produce in a distended hollow viscus a local rupture. It is also always to be remembered that the condition of a hollow abdominal viscus—whether full, half full, or empty—must have an important influence in determining the consequence of any external violence; so that where the local application of a force to a distended organ may in one case produce a fatal rupture, the application of the same or even greater force applied to the same viscus when empty will be followed by no serious result. In all abdominal injuries it is well, therefore, for inquiry to be made as to the relation of the time of the accident to that of the antecedent meal or act of micturition, since with the knowledge so acquired the diagnosis of a case is helped and made more certain, and its treatment is more likely to be successful. Again, it must always be acknowledged that in any example of abdominal injury a liver or spleen may be fissured or even crushed without giving rise in its early hours to any such symptoms as will lead the surgeon in attendance to diagnose the presence of such an injury; although when collapse has immediately followed the accident and the force which has been applied to the abdomen has been great, and when the state of collapse persists or becomes more marked, some suspicion of its presence should certainly be excited; or, again, should, as the early hours pass without shock, a sudden collapse occur, fatal or otherwise, the fear of a secondary hæmorrhage having taken place must arise; or, as days pass, symptoms of peritonitis show themselves, the probability of the breaking down of some bruised or injured tissue should not be overlooked. Again, a hollow viscus may be bruised or partly torn, but not through all its coats. At one time the serous covering may be split, but not the mucous; at another the reverse condition may exist; and under such circumstances, if the case be rightly treated, all may eventually go well. In a hollow viscus, where the mucous membrane lining its lumen has been torn away from its muscular and serous coverings, symptoms would exist which should be recognised, and with such an injury complete repair may be obtained. Cases will be quoted to illustrate these points.

The chief effects of any abdominal injury as well as those which are the immediate causes of death may be enumerated as four—namely, shock, hæmorrhage, extravasation of the visceral contents, and peritonitis, the first two

Digitized by Google

and the last two causes of death being more or less intimately associated.

Shock or collapse is under all circumstances an alarming condition, since it always means a tendency towards death and suggests by its presence in any case of injury to the abdomen some serious visceral or vascular complication; and yet experience tells us that as a primary symptom in these cases it is often unreliable, for it is not uncommon to meet with examples of severe injury to the abdominal viscera which are associated with but slight collapse as an early symptom; and it is at least as common to find grave and at times prolonged shock present in the early hours of a case which eventually turns out to be one of quite a trivial nature. Nevertheless, shock or collapse is always indicative of danger, and if not evanescent had better be interpreted as a significant sign of some serious visceral or vascular complication with or without hæmorrhage. Again, collapse in some instances of abdominal injury may pass away wholly or in part, to return either slowly or suddenly after the expiration of a few hours or days. This form of collapse should be called "relapsing collapse," and when it occurs it always means mischief, and probably serious mischief, for it either indicates the existence of secondary hæmorrhage or the giving way or separation of some damaged tissues. Indeed, this relapsing collapse has for diagnostic purposes much the same value as that possessed by a persistent primary shock or collapse which immediately follows an accident, although the relapsing form indicates either a secondary hæmorrhage at the seat of injury rather than a primary, or some secondary giving way of a tissue which had been damaged by the accident but not at the time separated, this secondary separation of tissue being brought about either by an absence of repair at the seat of injury or by some ulcerative process. In either case the relapsing collapse is due to a secondary hæmorrhage or to the extravasation of the contents of some hollow viscus, or it may be to the combination of both. By way of conclusion it may therefore be accepted that in every case of abdominal injury in which shock or collapse is a prominent symptom it is reasonable to entertain a fear that either hæmorrhage or visceral rupture may be the cause. If the symptom persists or becomes more marked that fear must be strengthened and even become a certainty; although, on the other hand, the reverse does *not* hold good, since a serious and necessarily fatal consequence of injury may exist with only a very slight or evanescent indication of shock. Shock or collapse as a relapsing symptom is, however, always indicative of a serious complication.

Hæmorrhage as a consequence of an abdominal injury and as a cause of death is very common, although it must be understood that shock may be present in a severe, if not fatal, form without hæmorrhage. The symptom is thus clearly due to some effect of the injury acting through the sympathetic nervous system upon the cardiac plexus and so upon the heart. In my work on the "Practice of Surgery"[1] I quote two cases which seem to support this view. Such a conclusion should never, however, be accepted in any given case without the most careful and complete examination of the body after death. When collapse is persistent or becomes more marked the presence of hæmorrhage should be diagnosed, although its exact source may be a dark point. It may have come from a fissure, laceration, or crush of a solid viscus, such as the liver or spleen; it may have come from a lacerated or ruptured hollow viscus, or from some tear in a mesenteric or other vein or vessel. When collapse shows itself in the relapsing form it is certainly reasonable to conclude that it is due to a secondary hæmorrhage brought about either by the giving way of a vessel that was injured but not torn at the time of the accident, or to the separation of part of a solid viscus which was so crushed by the force which caused the injury as not to be followed by primary bleeding, but which as time passed and shock diminished subsequently separated, either as a consequence of some unfortunate movement which was allowed under a mistaken view of the nature of the case, or which was made without leave, or which took place during the muscular effort caused by defecation.

Extravasation of the visceral contents may take place either as a direct consequence of an abdominal injury or as a secondary result, this secondary result being due to the giving way of a part which might have been contused at the time of the accident, but in which there was no absolute solution of continuity, the subsequent rupture taking place by either the casting away of the contused tissue as a slough, or by a process of ulceration which has taken the place of repair at the part injured, or it may be by a rupture from over-distension of the injured hollow viscus. Under the former circumstance, when the rupture has been the direct result of the accident, it is more frequently than otherwise associated with hæmorrhage, and in the latter circumstances, when it has been brought about by secondary causes, it is more frequently than not associated with first a local and subsequently a general peritonitis. A full recognition of the truth of these preliminary observations ought to be present in the mind of every surgeon before he approaches a case of injury of the abdomen with a view to its diagnosis and treatment; and it is with this feeling very clearly fixed in my own mind that I now pass on to consider the difficult subject of diagnosis of an abdominal injury.

The Diagnosis of Abdominal Injury.

Although from what has been written a feeling of uncertainty must predominate in the mind of every surgeon when he approaches a case of injury to the abdomen with a view to its diagnosis, that of blank dismay as to success must not be allowed to reign, for with a methodical investigation of any case from first to last enough information will usually be obtained to justify the formation of a provisional diagnosis which will be sufficiently clear to sanction the laying down of a clear and scientific line of treatment, although both the diagnosis and the treatment based upon it may require modification as symptoms change and the true nature of the case by its progress becomes more defined. As a primary line of investigation the surgeon should, as already advised, as a matter of routine inquire in every case from those who may have witnessed the accident as to the character and degree of force which had been applied, with the direction of its application, and more particularly with reference to the position of the patient at the moment of its application and to its seat of impact, and these inquiries should be followed by the careful scrutiny of the clothes of the injured one; for by adopting these methods of preliminary inquiry valuable suggestions as to the probable nature of the injury may be raised which must prove of value in directing the attention of the surgeon into a right channel; indeed, with such evidence alone the surgeon will occasionally have for a time to be satisfied. The examination of the injured region should come next in order, and this examination should be very carefully undertaken with the full recognition of the fact that the gravest internal abdominal injuries may coexist with the slightest or even with no external evidence of mischief; and that marked evidence of external mischief to the abdominal parietes may be associated with absolute immunity from injury of the abdominal contents. Should no external evidence of abdominal injury be visible after due inspection, the surgeon must not allow himself to be put off his guard, and more particularly when he has received reliable information from those who had seen the accident as to its true nature. Indeed, upon such circumstantial testimony the surgeon, for the time, may have chiefly to rely, not only for his provisional diagnosis, but for the line of treatment he should lay down, although that treatment may be simply one of expectancy, which will have to be modified by either the development of fresh symptoms or by the disappearance or modification of such general symptoms as may have been at first present. should marked ocular evidence of local injury be found—and this local evidence tallies with the circumstantial history of the accident which had been obtained and the general symptoms of shock or collapse which followed the accident—the diagnosis of serious internal mischief would be justifiable, although such a diagnosis would be either weakened if the general symptoms of shock or collapse had been but slight or of a passing character, or in the same way strengthened if the indications of shock or collapse instead of passing off had become more marked or of a steadily intensifying character—the persistency of shock or collapse, or its sudden or gradual intensification, being under all circumstances of abdominal injury a symptom of grave import, either with or without ocular evidence of local injury.

With respect to *vomiting* as an indication of mischief much might be said. The mere evacuation of the contents of the stomach after the receipt of the injury is to be looked for as a consequence of shock, and is not, therefore, significant, although should vomiting appear without the presence of shock it is a serious indication. When the

[1] Practice of Surgery, vol. ii., p. 684. Fourth edition.

Digitized by Google

stomach has, however, once emptied itself, its action, if the result of shock alone, should cease; consequently when vomiting persists or reappears after it has once ceased some serious intestinal mischief should be suspected. The earlier the appearance of vomiting after the receipt of the injury, and the more persistent the symptom, the greater is the probability of some rupture of the upper part of the small intestines. The later the appearance of vomiting after the injury the greater is the probability of the seat of rupture being lower down, for it is certain that the small intestine may be torn or perforated in its lower region, not far from the cæcum, without being associated with vomiting at any time, or should vomiting appear it will not do so for some ten or more hours after the receipt of the injury—that is, until some secondary shock has taken place as a result of extravasation of the contents of the ruptured bowel, or septic peritonitis has set in. When blood is found to be mixed with the evacuated material at the first vomit a suspicion of some injury to the mucous lining or other coats of the stomach should be excited. When it is absent in the early vomit and appears later the probability of some intestinal rupture high up, as in the upper extremity of the jejunum, is raised. Rupture of the large intestine *per se* is not in my experience attended with vomiting of blood, but rather with intestinal hæmorrhage.

The value for diagnostic purposes of the *passage of flatus* or its expulsion from the bowel per anum with or without motion deserves more than a passing notice; for, strange as it may seem, it is but true that a patient with a lacerated wound of his ileum 3 ft. from the cæcum, and who died on the eighteenth day, had two natural actions of his bowels during this period. A man who had a rupture of the middle of his ileum from the kick of a horse, and who lived but forty-eight hours, passed flatus downwards freely. A man aged forty-one, who died on the fourth day from suppurating peritonitis due to fæcal extravasation the result of a complete rupture of the ileum 3 ft. above the cæcum, passed flatus freely and had a natural motion. A boy aged six who died six days after an injury produced by the treading of a horse, which caused a double perforation of his small intestine, one being 14 in. from the pylorus and the other 1 ft. lower down, had two natural actions of the bowels. A man aged twenty-one who lived eighteen days after the passage of the wheels of a heavily-laden van over his abdomen, which had ruptured his ileum above the cæcum, had two natural motions, although he died from peritonitis due to extravasation. And lastly, a boy aged sixteen who was hurt by the wheel of a cart passing over his abdomen, and died on the fifth day after the passage of a motion which was followed by collapse and death, was found to have had secondary hæmorrhage into the abdominal cavity from the separation of a mass of liver which had been crushed at the time of the accident, the muscular exertion which attended defecation having doubtless brought about this sudden death.

Pain as a symptom of diagnostic value is at times very confusing, for its absence is by no means to be accepted as being any evidence of the trifling nature of an abdominal injury, and its presence even to a marked degree supports no argument in favour of severe trouble; for pain in abdominal injuries is always to be estimated, as in all others after a due consideration of the personal equation. Still, persistent local or general abdominal pain is always a symptom of importance as well as of gravity. In most cases it is central and radiating. Pain seems to be, so far as its severity is concerned, about the same in injuries of the solid as of the hollow viscera; it may likewise be slight in visceral injuries and severe in integumental.

With these preliminary general remarks upon the causes, effects, methods of investigation, and diagnosis of abdominal injuries, I propose to quote the brief notes of such cases as may illustrate their truth; and first of all of the statement which is so important to bear in mind: That abdominal injuries which have been brought about by severe external violence, and are associated with external features and general symptoms which suggest grave internal complications, may in their progress prove that such an inference was incorrect and that the internal injury was really trivial.

CASE 1. *Severe abdominal crush without intra-abdominal mischief, but with hæmorrhage into the orbits.*—The patient was a man aged thirty-two years who was admitted under my care into Guy's Hospital on May 2nd, 1873, for an injury he had just sustained when cleaning his railway engine. The engine moved when he was at his work, with his abdomen resting upon its crank, and in so doing crushed him between the crank below and the body of the engine above. He was rendered perfectly insensible by the accident, as well as collapsed, and in that state he was brought to the hospital. His abdomen was found on his admission to be generally bruised, especially upon its left side, and his eyes were blackened from blood effused into the eyelids, as well as into both orbits, the blood coming forward from behind the eyeballs. There was, however, no paralysis. Consciousness returned in about ten or twelve hours, when he complained of intense abdominal pain, and his pulse improved. His urine, which was drawn off, was quite clear. As hours passed no fresh symptoms appeared, and with each day it became evident that his abdominal injury had not involved any viscus. In the course of a few weeks he left the hospital convalescent, although the subconjunctival hæmorrhage had not disappeared. It is to be noticed that in this case there was no vomiting, and that although the character of the accident more than justified a diagnosis of a serious abdominal injury, yet from the progress of the case it became clear that the viscera had escaped. The hæmorrhage into the orbits and eyelids indicated by its presence that the abdominal pressure must have been very severe, the bloodvessels having doubtless ruptured from their over-distension brought about by the abdominal pressure. I have, however, seen this orbital hæmorrhage before in a case of crushed thorax, but with it there was also bleeding from both ears; recovery likewise took place in that case.

The next statement I wish to prove is the reverse of the last, and that is that the gravest internal abdominal injuries may coexist with the slightest or with no external evidence of mischief, and even without shock or collapse.

CASE 2. *Ruptured liver; death on fifth day.*—In October, 1883, a boy aged sixteen walked into Guy's Hospital after having been run over by the wheel of a cart which had passed over his abdomen. The boy, although in pain, had walked at least a quarter of a mile to the hospital after the accident. When admitted he was pale and in great pain, but his pulse was full and there were no external signs of injury. When put to bed he vomited, but there was no blood in the vomit. His urine, which was passed naturally, was clear. On the second day his abdomen became more distended and hard. His pulse was 104. On the fourth day he passed flatus downwards, but no motion. On the fifth day he rested with his legs outstretched, but rather to the right side, and later on the same day he had an action of the bowels, which was accompanied with severe abdominal pain and speedily followed by collapse and sudden death. After death a fissure three inches deep was found in the right lobe of his liver, filled with blood-clot and covered with lymph. There was also evidence of slight peritonitis about the seat of injury. It seems more than probable that in this case recovery might have taken place if the straining for a motion had not been called into requisition.

CASE 3. *Ruptured spleen; death on twelfth day.*—A girl aged five was run over, a wheel passing over the upper half of the abdomen, and admitted into Guy's Hospital in 1873 with a fractured jaw and injury to the left side of the thorax, but without any evidence of abdominal trouble. No fracture of the ribs was made out, although it was suspected from the difficulty of breathing which was present from the first. The child seemed to be doing well and about the fourth day was able to sit up in bed. On the eighth day abdominal symptoms appeared suggesting peritonitis, and then, rapidly increasing, proved fatal on the twelfth day. After death, besides the fracture of the jaw, the fifth left rib was found to have been broken as a green stick, and there was some recent lymph about the left lung, and on separating the intestines, which were distended and inflamed, some four or five ounces of grumous blood were found about the spleen, which was ruptured on its anterior edge. In this case there was no evidence whatever of intra-abdominal injury, and nothing except the nature of the accident to suggest the probability of its presence. The development of peritonitis raised the question very definitely, although the true cause of the abdominal mischief was only revealed at the necropsy of the case. The case shows very clearly that a spleen may be ruptured by some external violence, and that the symptoms primarily associated with such an injury may be absolutely negative.

CASE 4. *Ruptured jejunum.*—That a bowel may be partially or wholly divided as the result of an injury, and yet

Digitized by Google

be associated with no such severe symptoms as to suggest the true nature of the accident, is a truism which should always be recognised. Thus, a man aged forty walked into Guy's Hospital on June 23rd, 1877, after having received a kick from a horse on his abdomen. He appeared to be so slightly injured that his friends wished to take him home, for he was neither sick nor collapsed and only complained of local pain where he had been kicked. As a means of precaution he was, however, put to bed, although to die within thirty-six hours from acute peritonitis. At the necropsy, besides evidence of general peritonitis, intestinal contents were found in the peritoneal cavity, and great difficulties were experienced in finding the seat of the rupture; indeed, the bowel was carefully looked through twice without success, and it was only by distending the bowel slightly with water that the leak was found in the small intestine through an opening about a sixth of an inch in diameter situated about three feet below the duodenum. The edges of the opening were everted, and the opening was covered with lymph.

CASE 5. *Ruptured ileum.*—A man aged forty-nine when working at the river-side was knocked down by a falling bale of wool and doubled up. He was at once taken to Guy's Hospital, when he was so free from pain and shock that he walked up two flights of stairs to the ward. When examined a fractured clavicle was found, but there were no indications of any other injury. As a matter of precaution the man was kept in the hospital for the night, when about ten hours after the accident he suddenly became collapsed and died in two hours. At the necropsy some slight ecchymosis was seen over the abdomen, and upon opening this cavity the intestines were found partly covered by omentum and matted together by lymph and blood mixed with some fæcal matter. A portion of intestine six feet from the cæcum and situated beneath the umbilicus was found to be lacerated on its mesenteric side for two-thirds of its circumference, and through this rupture extravasation of fæces to a very limited extent had taken place. There was also evidence of local peritonitis at the seat of injury.

CASE 6.—A boy aged thirteen, after a blow on the abdomen, walked a mile with but little assistance, and when he died—thirteen hours after the accident—the duodenum was found to be completely torn across.

CASE 7.—A man aged twenty-five walked into Guy's Hospital after receiving an abdominal injury and complained only of local pain. He lived thirty-six hours and died collapsed. After death his duodenum was found to be ruptured.

These brief notes of seven cases are enough to prove the point for the illustration of which they have been quoted, and they should so impress the minds of all surgeons who read them as to lead them to accept the statement that the gravest internal abdominal injuries may coexist with either the slightest or with no external evidence of mischief, and even without shock or collapse or other general symptom to suggest their presence. With this assurance in their minds surgeons will then recognise, more than probably some do now, the value and importance of the history of every case of abdominal injury, and thus be led to regard as probable what might otherwise have been regarded as vaguely possible—the presence of grave intra-abdominal mischief, with the absence of grave symptoms, when the nature of the injury has been such as might reasonably have been expected to have brought it about. With this view predominant in the surgeon's mind a careful expectant treatment would naturally be adopted and much harm consequently be avoided. In the cases which have been quoted the truth of this conclusion has been well demonstrated.

Grosvenor-street, W.

FOOTBALL CASUALTIES.—Last week, in a match between the Fishpond and Bristol teams, a player for the former sustained a fracture of his leg.—On Saturday last the following accidents occurred: During a match at Egerton Park, Hopewood, between the Heywood Rovers and Ramsbottom teams, a full-back player for the home team fractured his clavicle.—The captain of the Royal High School team, and last year one of Scotland's three-quarters, in a match between the School and the Stewartonian teams, fractured one of his ribs.—During a match at Lawrence-road, Wavertree, between the Toxteth and Huyton Quarry Clubs, a player of the latter club fractured his leg and was removed to the Southern Hospital, Liverpool.—In a match at Rochdale, a player with the Horridge Club received such serious injuries to his head that he died on Monday last.

ON THE SENDING OF PHTHISICAL PATIENTS ABROAD.

BY SAMUEL WEST, M.D. OXON., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL; SENIOR PHYSICIAN TO THE ROYAL FREE HOSPITAL.

AUTUMN is full upon us and has displayed almost winter severity, and with the change in the weather comes the important question of deciding upon winter quarters for our phthisical patients. "Go abroad" is advice so easy to give and often so difficult to follow. I propose to consider what are the difficulties in the way of acting on such good advice. I shall assume that it is best for a phthisical patient to winter in a good climate if possible, but I shall not discuss the different winter resorts or compare them with one another. I shall devote attention chiefly to those individual or personal factors in the problem which constitute its real difficulty, and upon the due appreciation of which the value of the advice given depends.

Climate is not a cure for phthisis, but it may help a phthisical patient to get well. There is probably no place on earth where phthisis cannot exist, and though where the air is pure and the conditions of life sanitary there will be little phthisis or none at all, still even there if the conditions of life are altered and if they become less sanitary or even unwholesome phthisis will develop or increase. Thus it is that there is more phthisis in towns than in the country, and in the crowded parts of the same town than in the less crowded parts of it. Even in Australia, which was once thought to be free from phthisis, it is now becoming the same scourge it is elsewhere, and especially in the large towns. Sunlight and fresh air are potent remedies for phthisis, and those places are best for phthisical patients where they can be longest out of doors in bright sunshine and in pure air. A good climate is a place to get well in or to convalesce in, and in order that a phthisical patient should derive full benefit from such a climate he must be more or less convalescent—i.e., getting better, or at any rate not getting worse. In other words, the phthisis must not be in the acute or active stage. Even in the best of climates the patients must still be treated as invalids or convalescents, and must be taken the ordinary care of such as prudence and common sense would suggest. No climate is perfect, none will do away with the need of care; yet how many patients suffer by not knowing or disregarding this—by acting as if the climate would do the impossible, running risks and doing things which at home none but the healthy and strong would do, and such as an invalid should never attempt.

The question of going abroad is a very serious one. It involves the abandonment of the ordinary occupations and perhaps the loss even of the means of livelihood, the breaking up of the home and family it may be, and the expenditure of much money. This, therefore, is a question not to be lightly decided. It requires the greatest deliberation, and into it enter many considerations besides those which are purely medical. It is often a question of not what is the best in the abstract, but what is the best possible under the circumstances in which the patient is placed. In every case the question must be answered with a special reference to the individual concerned, and cannot be settled on general principles, for however true such principles may be in general they often lead to the gravest error in practice if applied indiscriminately and without special consideration to an individual case. Patients often go to a medical man expecting him to decide offhand. This is sometimes attempted, and not infrequently with lamentable results.

There are several questions to be answered before the right conclusion can be arrived at. 1. Is the patient in such a condition as to be likely to derive permanent benefit from a better climate than he has at home? 2. If he is fit to travel, how long a journey can he undertake, and what kind of travelling will be the best? 3. What are his means (for foreign residence is largely a question of money)? 4. How long can he stay away from home? 5. Who can go with him? 6. When shall he start and how shall he go? 7. What kind of place is likely to suit him best? 8. What is the patient's general character, and how will it be affected by living in a foreign country, with houses, customs, and food all strange to him? 9. How

Digitized by Google

can he occupy his time or amuse himself? 10. What effect will separation from home and family have upon him? 11. As regards the place, we must consider: (*a*) how far it will meet the various requirements already specified; (*b*) whether the patient is in a condition to derive full benefit from the advantage it offers; (*c*) the accommodation the place affords for an invalid in respect of housing, food, and general comforts; and (*d*) its accessibility, not only in respect of the journey out for the patient, but for the journey home should the patient decide to return, and especially with reference to the coming and going of friends, visits which go so far to make absence from home tolerable.

This is a long string of questions to be considered, but many others, too, of less importance will easily suggest themselves, and, small as many of them may seem to be, it is just upon such trifles as these that the whole comfort of the invalid depends and the success or failure of the sojourn abroad turns. All these questions must be considered carefully if wise advice is to be given. The medical adviser must, in fact, put himself in the patient's place and regard the question from his point of view, taking into consideration all these personal facts in the problem as well as the medical aspects of the case, and according as he does this or not will his advice be wise and beneficial or the reverse. The most disastrous mistakes are often made by sending patients abroad without careful thought—disastrous alike to the patient, to the family, and to the practitioner's own reputation. Even with every care the difficulties of a right decision are often enormous, but those who take most care will make fewest errors. The light and almost flippant way in which patients are sometimes advised to go abroad, with little or no regard to the special circumstances of each case, is often cruel in its results and cannot be too strongly reprobated.

If the patient is to benefit by a good climate his condition must be such that he may be able to take full advantage of it when he gets there. A patient, therefore, who is in the acute stages of disease, who is too ill to be up and spends all day in bed, is obviously not a case to send abroad, nor is he either fit to travel. He is best at home, where he can be carefully nursed and tended. Even if he is less ill than this and able to be up part of the day, though with a temperature above normal every day and with marked constitutional signs, he is best at home. In these respects the constitutional condition of the patient, rather than the physical signs, is our best guide. If, on the other hand, the temperature is not much raised and the strength fair, so that the patient may be a good deal out of doors every day when the weather permits, he may fairly be sent abroad. Of course, the most suitable cases of all are those in which the constitutional symptoms are entirely absent and the disease stationary, and this is true in any stage of the disease whatever the physical signs may be.

The next question is, What kind of a journey can the patient stand? This often limits greatly the choice of place. Some journeys are obviously out of the question on account of the exposure or fatigue they entail. If the journey is too long to be travelled right through at once it may be broken at convenient places. In some journeys, such as that to the Riviera, the arrangements are so well made for invalids that they can travel easily right through in comfortably warmed and ventilated carriages, but even such a journey as this is tiring and may be more than the patient can stand. If the journey be broken the breaks must be carefully timed and thought out, so that the patient may not be exposed at night, especially in chilly or cold weather. In this country, unfortunately, all journeys abroad involve crossing the sea, and there is nothing worse for invalids than waiting on draughty piers and in railway stations, on landing or going on board, when the day is cold and windy or at night time. In some instances a journey by ship all the way is an easier mode of travelling than by railway; still, the patient ought to be a good sailor and the weather promising. It can do no invalid good, whether a good sailor or not, to be under closed hatches for some days in a cabin or saloon which is poorly ventilated and perhaps shared with other invalids too; still, in good weather and on a good vessel travelling by steamer is one of the easiest and best modes of making a long journey.

Perhaps the most essential question is the means of the patient. Can he afford to be away from home some time without anxiety as to cost, to travel in every comfort as an invalid should, and to have every comfort in the place of destination in respect of housing, food, amusement, and attendance? To go abroad as an invalid is a very expensive business whatever be the place chosen and often involves an outlay of from £300 to £500. It is often better for the patient to be at home, surrounded by the usual comforts and occupations, than to be without them in a good climate, and to be able to afford only a second-rate accommodation, food, and attention, and to be obliged to economise in the small comforts and luxuries which could be provided at home. To be abroad and worried by such petty cares will undo all the good a good climate might do.

It is useless to send phthisical patients away for only a month or two. They should leave in October and not return until May or June. Of course, they need not stay in the same place all the time. They may, for instance, spend the autumn in Geneva or at the Italian lakes, and make their way to the Riviera as winter sets in, going up perhaps to the mountains as the heat of spring and summer comes on. At any rate, the whole winter must be spent away, and if the first proves a success possibly a second and a third. All this means money, and on this score the mind must be easy if the climate is to do good.

If the patient is a young man who is fairly active he may go abroad to settle and alone, but in other cases a companion will be needed, and the question is, Who else can go? Preferably, of course, some member of the family should be selected, for it is difficult to find a paid person who will at the same time be a good companion and an attentive and skilful nurse. Even from among the family it is not always easy to find a companion congenial to the patient. One of the great difficulties to be dealt with in arranging to send a patient abroad is the way in which it breaks up the home. If the mother is the patient she will have to take her daughter with her, perhaps the one who naturally would fill her place when she was away. Or if the daughter is sick and the mother has to go, she will have in most cases to leave her husband alone, whose profession or business makes it impossible for him to be long away from home.

Closely connected with the question of companionship is the character of the patient, whether he is of a cheerful and sociable disposition and inclined to make the best of what he even does not like, or whether he is morose and despondent, inclined to take a despairing view of most things and to magnify the discomforts of being away from home. Few persons like to be sent abroad for their health. Some may enjoy it if well enough; but these are generally young people with no special responsibilities or cares, to whom the novelty and change of life are full of interest. Most other persons look upon it as exile, and to those of a despondent nature home sickness and the petty discomforts and trials of foreign residence often make the life intolerable to them. Again, some occupation must be provided if the invalid is not to suffer from *ennui*, for time often hangs heavy on a sick man's hands. Open-air exercise and occupation are the best of all if the invalid is well enough to enjoy them; but if not so, it may often be difficult to keep the patient occupied and happy. It will also be necessary to consider what the effect will be upon the invalid of leaving home, family, and friends. Many patients feel and say that they would rather live a shorter time at home, with their family and friends about them, than a longer time abroad, separated from all that makes their life worth living. To banish a phthisical mother from her family and home is often cruel, and almost as often ineffectual, for the craving for home and the grief of separation produce more harm than the climate does good. Due allowance must be made for this personal question. A compromise may be sometimes made with advantage by choosing a place not too far away where the mother, for instance, may feel that if necessary her children could always come to her, or if need be she could go to them. The idea of absolute separation is sometimes unbearable, and the fear which some patients have lest they should die abroad not infrequently decides them against a foreign journey.

If these preliminary questions have all been satisfactorily answered we have next to consider what place will best fulfil the requirements, bearing in mind especially the kind of life the patient is likely to lead, whether he will be much out of doors and lead a more or less active life, or whether he is incapable of much exertion and must lead a more or less sedentary life when out of doors. In the latter case the place must be warm, but in the former it may be colder and more bracing. The idiosyncrasies of the individual again

Digitized by Google

must not be forgotten. It will be well to ascertain what kind of place has hitherto suited him best, whether a high or low place, a hot or cold place, a bracing or a moist and more relaxing air. Speaking generally, phthisical patients are best in a warm but not hot place fairly high up and with a more or less bracing air; at any rate, great heat and great moisture do not suit most.

With respect to the place especial consideration must be given to its accessibility and to the accommodation available. In regard to accessibility we have to consider, not only the distance of the place and the time it takes to reach it, but also the means of travelling thither. Some places comparatively near, like Davos, are more troublesome to get to—at any rate, at certain times of the year—than those further away, like Madeira. There is also to be considered the ease with which the patient's friends and relatives can make the journey to and fro, and the facility offered for the patient's return home if it should be necessary. Nervous patients often object strongly to the feeling of being locked up in a place from which they could hardly move, even if it were necessary, until the winter was over. The accommodation is also an important factor, for some excellent climates are quite unavailable for the want of such hotels or dwellings and such cooking or comforts as an invalid must have. For these local details local knowledge is necessary, and it is well for patients to put themselves into relation with the medical man of the place as soon as they arrive, so that they may obtain the best advice as to the part of the town to live in and the actual lodgings and rooms available. A great deal turns on these points, and the information can only be supplied by a resident in the place with the necessary knowledge.

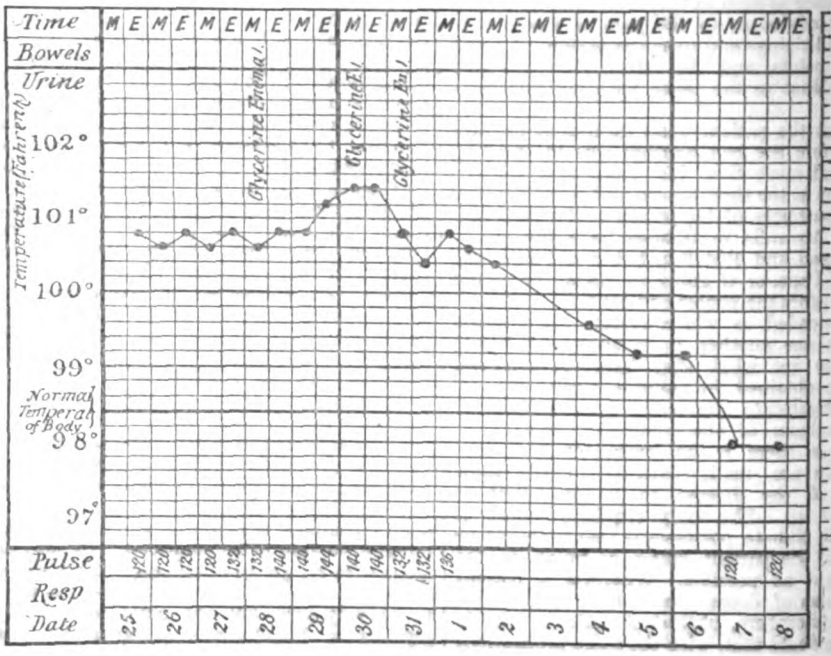
If it is settled that the patient shall go abroad he must leave the country before the bad weather sets in—that is, before November—and must time his journey so that he reaches his destination at the right season and is not exposed on the way to great extremes of temperature; for instance, if he were going to Australia in October he would not go through the Suez Canal and Red Sea, but would take the voyage round by the Cape, or if going to Davos he would arrange to get there before the winter had set in.

The places recommended as winter resorts for phthisis differ so much from one another in respect of climate that it is difficult to see what they have in common, yet good results are obtained in suitable cases with all alike. Statistical statements are most unreliable—first, because of the smallness of the numbers dealt with, and, secondly, because there is no guarantee that the cases in each group are really patients in the same stage or condition of the disease so as to admit of fair comparison *inter se*. The only requisite which it appears every suitable climate possesses is that it should be such as to admit of the patient being as much in the open air and sunlight as possible. Wherever a patient can spend all day out of doors, and when indoors can still live in a pure atmosphere, phthisical patients will do well; and I have little doubt that, with the same precautions and subject to the same *régime* that phthisical patients voluntarily submit to abroad, they might easily live and benefit in many places at home in spite of our cold winds, moist air, and comparative want of sun in winter.

I may conclude, much as I began, by stating that in this question of wintering abroad we have to decide not what is best in the abstract for phthisical patients in general, but what is the best possible under the circumstances for a particular case. What these circumstances are will take time and trouble to investigate, but they are the prime factors in the problem. To come to the right conclusion in any given case requires some knowledge and experience, much care and trouble, and, most of all, sympathy and common sense.

Wimpole-street, W.

BRITISH COLLEGE OF PHYSICAL EDUCATION.—A meeting of the governors of the British College of Physical Education was held at the office of the college, 83, Lancaster-gate, on Saturday last, when it was decided that the college should be incorporated under the regulations of the Board of Trade, that no members or licentiates should be admitted to the college without examination after Jan. 1st, 1896, and that the next half-yearly examination should be held at the People's Palace on Saturday, Nov. 30th. A subcommitte was appointed to suggest the names of eminent men to lecture on physical education.



A CASE OF TRAUMATIC TETANUS TREATED WITH TETANUS ANTITOXIN; RECOVERY.

BY NESTOR I. C. TIRARD, M.D., F.R.C.P. LOND.,
PHYSICIAN TO KING'S COLLEGE HOSPITAL AND TO THE EVELINA HOSPITAL FOR SICK CHILDREN; PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, KING'S COLLEGE.

DURING my vacation in Arran I heard incidentally on a Sunday morning (Aug. 25th last) of a case of "blood poisoning" after an injury to the foot. I was told that the patient was the daughter of a butcher at Corrie, and had already been seen by two medical men, who had given a fatal prognosis. When passing the house later in the day I was hastily summoned, and found the child, a girl aged four years and a half, in a state of opisthotonos, the lips blue, the face cyanosed, the eyes turned upwards, and the conjunctivæ insensible. I could not detect any pulse at the wrist, and respiration was arrested; on listening over the heart, however, feeble, slow pulsations were heard. Under the influence of a hot bath respiration gradually recommenced, the appearance improved, and the pulse gained in frequency and in force. The spasm of muscles relaxed to a moderate extent only, the legs remained extended, and the muscles of the calf and thigh were rigid; the muscles of the upper limbs were also firm, but the hands could be moved slightly. The muscles of the abdomen were in strong contraction, the recti being prominent. Respiration appeared to be effected entirely by the intercostals, but the movements of the diaphragm (if any) may have been masked by the condition of the abdominal walls. When the immediate anxiety about the patient was somewhat relieved I learnt that, in running about with bare feet, she had cut her left foot badly about a fortnight before, there had been a great deal of hæmorrhage, and the mother had succeeded in extracting a piece of glass, which she thought was part of a broken jelly jar. The foot had been bound up and had been thought to be healing nicely for a week, and then lost its healthy look and did not progress. It was possible that in the interim the child might have played in the slaughter-house or in the adjoining stables. During Aug. 20th, 21st, and 22nd she had not been as cheerful as usual, she had lost appetite and had been much quieter, but no medical man was sought until Aug. 23rd, when she had a succession of severe convulsions. She was then seen by Dr. Neil Fullarton of Lamlash, who at once recognised the case as undoubtedly one of tetanus and ordered the foot to be poulticed. He also commenced treatment with six grains of chloral hydrate every four hours, and a chlorate of potash gargle was tried, as the tongue appeared to be very sore, but the child refused to employ this, so glycerinum boracis was substituted. Between the 23rd and the 25th she had numerous severe convulsions and was seen by a German medical man staying a few days in Corrie, who agreed with the diagnosis. Much difficulty had been experienced in attempting to induce her to take the chloral; the violent convulsion which I witnessed was attributed to the excitement of endeavouring to persuade her to take it from a spoon. The mother showed me the injured foot; there was a deep cut nearly three inches long, extending transversely across the inner side and sole of the foot about an inch behind the big toe; the wound was granulating and looked fairly healthy, and no foreign substance could be detected with a probe. There was no tenderness or swelling along the course of the lymphatics. I left a note for Dr. Fullarton, who lived ten miles off, explaining the circumstances of my examination of his patient, and on my way homewards telegraphed to my friend Dr. Hewlett at the British Institute of Preventive Medicine for some tetanus antitoxin. Through the kind help of Mr. James Coats, who placed his steam yacht at my disposal, I was able to obtain and employ the antitoxin within twelve hours from the time it left London. During this interval there had been three severe convulsive spasms, none of them so alarming as the one I had first seen, but the general condition remained very much the same. The child was conscious and could speak in short sentences, not using more than three or four words, and then only to call for milk, or water, or to beg to be taken up or else

Digitized by Google

put back to bed. She was extremely restless and fractious. The mouth was drawn up at the angles, the masseters being firm and rigid; the jaws could not be voluntarily opened beyond a third of an inch, and through the aperture the tongue could be seen to be much marked by the teeth and with an aphthous white membrane over the upper surface and yellowish sloughy patches on the lower. At the time of the convulsive spasms the jaws were always firmly clenched, and the tongue appeared to be driven forwards against the teeth. So far as I could ascertain the tongue had not been bitten; its condition resulted from the damage done by pressure in the course of convulsion. In addition to the three severe convulsive spasms above mentioned there had been very numerous little "starts" in which the only difference was the short duration; they would commence with a short stifled cry, then the body and limbs would become rigid and the respiration would be arrested momentarily, and then the spasm would partially relax. The feet could be bent slightly, but the general tonic rigidity of the calves and thighs persisted, and the abdomen remained firm and unyielding. During the intervals there was frequent complaint of epigastric pain, but there was no special tenderness on pressure, and the pain appeared to be similar to that so often met with after severe spasmodic cough. This, then, was the general condition when I obtained the antitoxin. Some difficulty was

experienced in powdering the ten grains, the dose employed, as the arrangements in the cottage were distinctly primitive. In place of distilled water I had to be content with water which had been freshly boiled and allowed to cool, but I found that prolonged patient stirring was needed to dissolve the ten grains in a fluid drachm of water, and then, having only an ordinary hypodermic syringe at hand, the dose was injected under the skin of the front of the left thigh, the needle being kept in position while the syringe was refilled. Beyond the momentary pain with the first insertion of the needle, the injection of this quantity of fluid gave very little discomfort, the resulting swelling speedily becoming somewhat reduced in size. The first injection was made at 11 P.M. on Monday, Aug. 26th, and the condition of the child remained very much the same during the night. At 2 A.M. she had an opisthotonic convulsion and another at 4 A.M., but according to the mother's account these, though bad, were not as severe as the convulsions she had had the previous day. At 10 A.M. on the 27th a second dose of ten grains was injected high up on the right thigh; there had been no material change in the temperature, but the child was perspiring profusely about the head, neck, and thorax. The pulse was still of good quality, and nourishment was well maintained by milk, which was frequently asked for. The day passed quietly enough, though the slight "starts" were frequent and the tonic spasm had not materially relaxed. A third injection of ten grains was made in the left thigh at 8 P.M. on the night of the 27th. The child was very restless during the night, constantly asking to be taken up and frightened if her mother left her for a moment. At 6 A.M. and at 8 A.M. she had convulsive attacks, but these did not last long. At 10 A.M. on the 28th a fourth injection of ten grains was made in the right thigh. The sites of the former injections were still swollen and discoloured like bruises; they were also somewhat tender. A glycerine enema produced a slight motion. During the day the child appeared to be much better and brighter, and when I saw her at 7 P.M. the only unfavourable sign (as compared with previous days) was an increased frequency of the pulse. The thighs now looked so swollen that I thought of injecting a fifth dose into the buttock, but as she was being turned over a very severe opisthotonic spasm occurred, and the breathing stopped, the lips became purple, and the conjunctivæ insensible; for the moment I thought the child was dead, but the heart could still be heard beating feebly, and on putting her hurriedly into a hot bath breathing again became re-established and the spasm relaxed. Not to disturb the child more than I could help, the fifth dose of ten grains was injected into the front of the left thigh near the knee. She passed a fairly quiet night after this, only being disturbed by slight convulsive starts. At 10 A.M. on the 29th a sixth injection was made in the right thigh above the knee. At this time it was found that the muscles of the calves were much less tense and the mouth could be opened a little more. Slight spasmodic starts occurred during the day, and when seen at night she was found to be covered with numerous sudamina, some reddened, giving the appearance of a punctate rash. She complained of much irritation about the forehead and scalp. The temperature was 101·2° F., the pulse 144 and more feeble. Whisky in half-drachm doses was accordingly given at intervals with the milk. On the morning of the 30th the temperature was 101·4° and the pulse was still feeble. A glycerine enema produced a copious motion, pale and formed. Patches of urticaria were found on the thighs in the neighbourhood of the injections, but the swellings had almost entirely subsided and only one of the sites of injection retained a bruised discolouration. On the morning of the 31st, at 6 A.M., a slight opisthotonic spasm occurred, but when seen at 10 A.M. the calves and thighs were much more flexible, and although the masseters could still be felt as firm bands there was not so much distortion of the features. The abdominal wall remained tense, and there was much complaint of pain over the epigastrium. Another glycerine enema again resulted in a copious evacuation. During the day there was much trouble with mucus in the mouth, which was ejected with blowing efforts. The accumulations of mucus gave much

Digitized by Google

istress, and several slight starts occurred after efforts at xpulsion. During the afternoon the child appeared much asier, holding a feather in her hands and playing with it. he limbs were not so rigid; she could draw up the thighs n bed. She slept at intervals and was noticing more. The vening temperature was 100·4°. On Sept. 1st there was still uch mucus coming from the mouth, and occasionally this as blood-tinged. The child slept during the greater part f the day, sometimes waking with a convulsive start, but oing to sleep again almost at once. On Sept. 2nd her conition had much improved, but she was still troubled with ucus. The temperature was 100·4°. On Sept. 4th the emperature had fallen to 99·6°. Much blood came from he mouth with the mucus. She played with her toys, but lid not talk. During sleep the mouth had been much more pen, and the pained look had left her face. On Sept. 5th after a quiet morning she had a slight pisthotonic spasm on being suddenly startled. The temperature had fallen to 99·2° and the pulse had gained in volume. Later in the day she talked to her brothers and played. The abdominal muscles were still somewhat rigid. She could urn in bed. During the night of Sept. 6th she had a slight spasm, in which she seemed to be in pain, but she went to sleep almost immediately afterwards. A similar slight spasm occurred on the afternoon of the 7th, but the temperature was then only 98°. I examined her for the last time on the evening of the 8th, and although not completely healed the wound in the foot was much smaller and looked healthy, and although there was much sense of resistance over the epigastrium there was no complaint of tenderness. She could move freely in bed, and when seated on her mother's knee her legs hung down freely, with bent knees and flaccid calves, but she was unable to sit up unaided. I considered her convalescent and returned to town, convinced that it would be only a few days before I should hear of complete restoration to health. On Sept. 10th the mother wrote that the patient "is getting on nicely; she can sit on my knee to-day without any support ..... she has not been one bit stiff to-day." On Sept. 12th she wrote that she "is still improving; I see such a difference in her every day; she takes little spasms yet, but they don't last any time, and she does not get stiff under the knee. ..... When I was lifting her out of the bed she put her arms round my neck and lifted herself up till she stood on her one foot." On Sept. 16th she said the patient "is able now to lie on either side and sit alone in bed. ..... She only cried twice with pain during the night; she has not any pain during the day." On Sept. 19th she further wrote: "She is able now to creep on her knees from one end of the sofa to the other; she can turn herself any way. ..... The skin has come off her hands, feet, knees, part of her body, and behind her ears." Finally, on Oct. 2nd, she wrote saying that she "can walk alone now, but she is still lame. I do not know whether the lameness is from weakness or that she is afraid to bend the sole of her foot. The foot is quite healed up, but it seems to be tender. She has no pains in her stomach nor anywhere else. ..... There is no twitching of any kind. ..... She plays with the others and is as bright as any of them."

Remarks.—The points of especial interest in this case are the following:—1. The proximity of stable and slaughter-house, which afforded possible sources of contamination of the wound. 2. The readiness with which milk was taken throughout the course of the illness. 3. The degree of spasm of the abdominal and respiratory muscles; this gave rise to the urgent symptoms quite at the beginning and also constituted the chief feature during the later stages; tonic and spasmodic contractions of these muscles persisted long after the muscles of the limbs had become flaccid. 4. The amount of mucus and blood coming from the mouth. Although the tongue was obviously sore and injured quite early in the case, this over-secretion of mucus only became manifest some days after the antitoxin had been used. 5. The excessive perspiration and the sudamina also were only noted after the antitoxin. 6. The severity of the convulsions as well as the frequency became much reduced after the antitoxin, though one of the worst attacks occurred on the 28th. The slight rise of temperature may have been due to the antitoxin; the urticaria was certainly, I think, a direct result. While it is extremely difficult to speak with certainty about the benefit of the antitoxin, I can only say that when I first saw the child I fully anticipated a speedy fatal termination, and this view was shared by two other medical men who saw her. Whenever we attempted to give medicines by the mouth so much excitement resulted that we had to desist. Certainly after the antitoxin the child was more peaceful, and the severity of the opisthotonic spasms was less.

Harley-street, W.

HEART FUNCTION AND PELVIC LESIONS IN THE FEMALE.[1]

BY JOHN D. WILLIAMS, M.D. EDIN., B.Sc.,
FREELAND-BARBOUR FELLOW OF THE UNIVERSITY OF EDINBURGH, 1888-90; LATE DEMONSTRATOR OF ANATOMY, SCHOOL OF MEDICINE, AND LATE PATHOLOGICAL ASSISTANT TO THE PROFESSOR OF MIDWIFERY OF THE UNIVERSITY OF EDINBURGH.

I WISH to confine my remarks, which will be brief, entirely to the so-called "functional" heart disorders. Of a little over 300 women whose hearts and pelvic organs I have examined during the last six years, and of whose cases I have accurate records in my possession, I have been able to gather twenty-five cases in which functional heart disorders were found clinically to coexist with obvious abnormal conditions in the pelvis. No case is included in these twenty-five in which there was a previous history of rheumatic fever or in which there existed organic valvular disease. Pregnancy and obvious hæmic conditions, such as are produced by profuse leucorrhœal discharges and abnormal uterine hæmorrhages from various causes, have also been carefully excluded. A careful analysis of the symptoms and clinical history of the twenty-five cases shows at a glance that the majority of the patients sought relief for troublesome symptoms referred directly to the heart, but it also indicates a minority who complained primarily of distress in the region of the pelvis. Some believed themselves to be the victims of heart disease from the construction which they themselves placed upon reflex submammary pain associated with a sense of throbbing or palpitation over the præcordium. Their ages ranged from seventeen to forty years. No case where the woman was above forty years of age is classified, in order to avoid the influences of the menopause. I shall not give a detailed account of each patient; it will be sufficient for my purpose to speak of them in groups arranged according to the particular pelvic organ affected.

Lesions of the uterus.—Of the twenty-five cases the uterus was affected in eleven instances. Eight of the eleven were patients in whom the uterus was displaced either backwards, forwards, or downwards. All these were married, and all except one, who was sterile, had borne several children. One of the eleven was a case of a rapidly growing abdominal uterine fibroid in a single woman aged twenty-eight years who had been under observation for two years. There was never any metrorrhagia, and but slight menorrhagia. The remaining two are cases of slowly growing pelvic uterine fibroids in women nearing the age of forty who complained of no pelvic symptoms of any kind and who were quite ignorant of their existence. All these women, however, suffered more or less acutely from symptoms and disturbances directly traceable to the heart in the form either of palpitation, throbbing, giddiness, pain and uneasiness over the præcordium separately, or of a combination of all. In some of the cases the heart's action was intermittent and in others it was irregular, the irregularity manifesting itself in a variation in the strength of the beat or in the time of the beat, and sometimes in a combination of both. In one of the cases of slowly growing pelvic fibroids—that of a married woman aged forty years—the nature of the cardiac derangement was very interesting. For ten, twenty, thirty, forty, and even fifty beats or more the heart's action was hurried. This hurried period was followed by a slow interval during which the cardiac beats were comparatively infrequent. These waves of hurried and slow action alternated, and in order to detect them it was found necessary to watch the pulse for several minutes. Also in this particular case variations in the blood pressure were observed to occur; for from one to three minutes the tension was high, and then there ensued a period during which the tension was low, which continued rather longer than the high-tensioned periods. These periods recurred in regular sequence. Such a pulse I have since occasionally met with

[1] Read before the South Wales and Monmouthshire Branch of the British Medical Association, February, 1895.

Digitized by Google

in women at the menopause. Whenever this patient rose suddenly from her bed or chair or abruptly turned round she was seized with giddiness, which lasted two or three minutes. Appropriate treatment, directed towards improving the position of the uterus, effected a complete cure of all heart troubles in five out of the eight cases of displacement already referred to. The three cases that did not improve were: (1) a married woman aged thirty-five years, sterile and suffering from pathological anteflexion of the uterus, with stenosis of the cervix and pin-point os; (2) another patient aged forty years, suffering from dysmenorrhœa and retroflexion; and (3) a woman aged forty years, suffering from prolapsus uteri, with multiple fissures of the cervix. Hysterectomy relieved the case of abdominal fibroid. The two cases of pelvic fibroids still remain unrelieved.

Lesions of the cervix uteri.—Two of the twenty-five cases were instances of stenosis of the cervix. One occurred in a robust, full-blooded girl aged seventeen years who had never menstruated and was suffering from severe face-ache, abdominal pains, and pains in the thighs, which lasted about five or six days and recurred once a month. At the same time she suffered from heart hurry and giddiness. I tried all kinds of medicinal treatment for fully six months, but to no purpose. Eventually I felt compelled to make a pelvic examination, when I discovered stenosis of the cervix. Subsequently the cervix was gradually dilated under anæsthesia, with the result that a few weeks later she menstruated for the first time, and without heart trouble. The other was a case of a sterile married woman aged twenty-nine years who was troubled with dysmenorrhœa, cervical stenosis, and menstrual headache and giddiness. Dilatation afforded no relief.

Lesions of the ovaries.—In six patients, all of whom were married and had borne children, one only being sterile, the lesion was ovarian. Inflammation and prolapse of one or both ovaries existed in five instances, the sixth being a case of a large-sized unilocular cyst growing from the hilum of the right ovary. Attention to the inflamed prolapsed ovaries and removal of the cyst allowed the heart's action to return to normal.

Lesions of the vagina.—A case occurred in a sterile, nervous married woman aged twenty-eight years who suffered from vaginismus, facial neuralgia, cardialgia, and severe palpitation. A lengthened but futile course of medicinal treatment was adopted. At last she consented to be anæsthetised and to have the ostium vaginæ forcibly dilated and cauterised with pure carbolic acid. This procedure was twice repeated. At the end of three months she was cured of all her bad symptoms.

Lesions of the rectum and anus.—Two married women, aged thirty and forty years respectively, the younger being sterile, were troubled with palpitation and a sense of uneasiness over the præcordium. The heart's action was irregular in time and strength, and there was an occasional abortive beat. They had for months suffered excruciating pain during and after defecation. Their suffering was due to a fissure. Surgical treatment under anæsthesia speedily cured the condition and effected in the course of a few months a complete restoration of health and strength and an absence of all cardiac trouble.

The remaining three cases of the twenty-five are as follows. 1. That of a multiparous married woman aged forty years who contracted influenza and three days later, when the fever was at its height, pelvic peritonitis. She was under treatment for six weeks and ultimately was quite relieved of her peritonitis, but she found after her convalescence was over that she became out of breath on the least exertion. On examining her heart I was astonished to find it beating at the rate of 120 per minute. I tried all sorts of remedies, but my endeavours were of no avail. She still suffers from tachycardia. Probably the influenza was the cause of both the pelvic and heart affection in this case. 2. That of a multiparous married woman aged twenty-five years troubled with pain in the lower part of the coccyx, inability to sit except by resting on one or other hip, painful defecation, tenderness and a sense of oppression over the præcordium, and palpitation and irregularity of the heart's action. When the local lesion was relieved her general health rapidly improved and the cardiac symptoms disappeared. 3. That of a married woman aged forty years suffering from a floating kidney and occasional attacks of giddiness and palpitation, with intermittent heart action. Strictly speaking, this ought not to find a place in the list, but still the wandering kidney may be regarded as simulating the influence of an abdominal tumour springing from the pelvis. No treatment was adopted beyond the use of an abdominal belt as the next best thing to nephrorrhaphy, and the cardiac symptoms are still unrelieved.

From the brief analysis above given, and I fear very imperfectly, it is clear, first, that relief has been afforded to the heart sufferings of seventeen women out of twenty-five in whom functional cardiac disorders coexisted with obvious pelvic and abdominal lesions; secondly, that this relief was afforded through directing attention to, treating, and curing the local lesion; and, thirdly, that some of the women here referred to sought medical advice under the firm impression that they were suffering from heart disease, and would hardly allow any reference to the pelvic organs as the seat of their complaint. As my chief object in writing this communication has been an honest endeavour to record accurately and faithfully the cases as they came under my observation, I shall not indulge in speculations or theories as to the possible modes by which diseased or displaced pelvic organs may influence the heart and the cardio-vascular system. That organic and functional cardiac diseases and pelvic lesions do coexist in the female in a moderately high ratio is an acknowledged fact. It is also recognised that the disturbances of the circulation in middle-aged women constitute a very considerable group of the functional disorders of the heart met with, at any rate in Great Britain and Germany.[2] In a previously published paper,[3] embodying the results of post-mortem investigations conducted by myself at the Edinburgh Royal Infirmary as to the frequency of the co-existence of valvular heart disease and pelvic lesions in the female, I have shown that organic cardiac disease is more frequently met with in women than in men, and that one of the chief differences of organic valvular disease of the heart in its relation to the two sexes is the great predominance in the female of mitral stenosis, and in the male of aortic incompetence, over all other cardiac lesions. The masterly and life-long researches of Sturges[4] into the heart affections in childhood show that cardiac disease is more often met with in young girls than in boys. Just as the metaphysical heart is more often accessible to a state of disturbance in the fair than in the sterner sex, so also its physical analogue, it is probable, is more frequently the seat of disease.

Cardiff, S. Wales.

FATAL ACUTE POISONING BY COCAINE.

BY O. H. GARLAND, M.D., F.R.C.P. EDIN.,
LATE SENIOR PHYSICIAN, LEITH HOSPITAL; SURGEON TO POLICE, &c.

THE following case is, I venture to think, of sufficient medico-legal interest to be recorded.

About 3.30 P.M. on Monday, Oct. 7th, 1895, at the request of the authorities, I made a superficial examination of the body of a young woman who had at about 7 A.M. swallowed for the relief of toothache upwards of two drachms of a ten per cent. solution of the hydrochlorate of cocaine, the equivalent of twelve to fifteen grains of the alkaloid. She had almost immediately afterwards suffered from vertigo, followed by epileptiform convulsions, nine in number, occurring in somewhat quick succession, and died within forty minutes. She appeared to be about seventeen years of age, and the body was well nourished. The trunk still retained a considerable degree of warmth, but the extremities were cold, rigor mortis being well developed in all of them. The face, lips, and anterior surface of the body were very pallid and waxlike, while on the dependent portions well-marked cutaneous hypostasis was present. The expression of countenance was placid. The pupils were dilated, and the conjunctivæ were not injected. The teeth were firmly clenched. On the following day (Tuesday), as further instructed, I made a post-mortem examination. The external appearances remained as described. Frothy mucus, slightly blood-stained, was freely exuding from the right nostril. The brain was anæmic, but otherwise normal. The meninges were deeply congested. The heart was healthy in substance, and all the valves were found to be competent. The right ventricle contained a

[4] THE LANCET, March 10th, 17th, and 24th, 1894.

Digitized by Google

small quantity of dark-coloured fluid blood, the left ventricle was quite empty. Both ventricular walls were relaxed. The lungs were much congested throughout and everywhere highly crepitant. A considerable amount of frothy mucus, in part blood-stained, was present in the bronchi. The liver, spleen, and kidneys were hyperæmic, but otherwise normal. The stomach and contents were removed and preserved intact for expert analysis, consequently there was no opportunity afforded for inspection of the mucous surface of that organ.[1] The bladder contained from three to four ounces of urine. All the other organs were normal.

Remarks.—The recorded cases of fatal poisoning by cocaine are comparatively few in number. Among these are that of a woman seventy-one years of age, who died five hours after the subcutaneous injection of two-thirds of a grain;[2] and the case of a man, mentioned by Haenel,[3] in whom the injection of one and one-third of a grain was followed by a fatal result. Zambianchi[4] also records a case where death occurred in a female after three grains and a half had been administered hypodermically. It is stated that a man died almost immediately after swallowing twenty-two grains.[5] Montalti[6] relates in full detail the case of a woman in whom death occurred after twenty-two grains accidentally swallowed. The first published fatal case in England was that of a man who was given in mistake twenty grains and succumbed in about an hour.[7] A fatal case occurred in Russia from a dose of twenty-two grains administered by rectal injection.[8] A melancholy interest attached to this case, as the surgeon who in mistake prescribed this overdose immediately afterwards committed suicide. Recoveries have taken place after very large doses taken into the stomach. The most typical case of the kind I am acquainted with is that of a man who swallowed forty-six grains and recovered.[9] On the other hand, serious symptoms of poisoning have been occasioned by the hypodermic administration of such doses as the seventh of a grain[10] and less than half a grain.[11] One-twentieth of a grain given subcutaneously to a girl gave rise to dangerous symptoms,[12] and a hundredth of a grain applied to the eye of a patient aged fourteen years has occasioned symptoms of poisoning.[13] The case I have above reported lends support to the correctness of Mannheim's[14] estimate that the fatal dose of cocaine is about fifteen grains. In the present state of our knowledge it is, however, practically impossible to state the smallest lethal dose, seeing that a dose of two-thirds of a grain has caused death, and so minute a dose as a hundredth of a grain has given rise to symptoms threatening life.

Leith.

[1] No analysis was made, as the Crown authorities were satisfied that the case was one of poisoning by misadventure.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

THE INFLUENCE OF INHERITANCE ON THE TENDENCY TO HAVE TWINS.

BY ROBERT COBY, M.D. CANTAB., F.R.C.P. LOND.,
ASSISTANT OBSTETRIC PHYSICIAN TO ST. THOMAS'S HOSPITAL.

THE following has been written to draw attention to the great factor of causation that inheritance plays in those who have twins. Like almost all of our inherited peculiarities, the tendency may come either from the maternal or from the paternal side. The relative frequency which either the maternal or the paternal side plays can only be established after considerable observation of cases. At present I have only collected seventeen cases. They include every case of twins I have investigated as to the above-mentioned point. Of the seventeen cases there is a history of twins to be obtained in 13, or 76·47 per cent. As the observations have been made almost entirely among the uneducated class this is a more remarkable fact than if they had been made among the more fortunate class, for the former class can rarely give any information of their families further back than grandparents. In eight cases the inheritance came from the maternal side only, or 47·06 per cent. In four cases the inheritance came from the paternal side only, or 23·53 per cent. In four cases there was no history to be obtained, or in 23·53 per cent. In one case there was a history on both sides, or in 5·88 per cent. When the inheritance comes from the father's side the twins seem to be always of the same sex, so far as the present observations go. This is interesting, for it is generally known that when the twins are joined together they are always of the same sex, and we may, therefore, reasonably suppose that this result is brought about by some abnormal potentiality of the spermatozoa — that is, this form of abnormality comes from the paternal side. The following is a table of the cases:—

Number.	Date of birth of twins.	Age of mother last birthday.	Birthday of mother.	Number of children, including twins.	Twins' sex.		Whether inheritance is on the mother's or father's side.	Condition of placenta.	Nearest relative who has had twins.
					First child.	Second child.

PUERPERAL SEPTICÆMIA: USE OF STREPTOCOCCUS ANTITOXIN.

By ANGUS E. KENNEDY, L.R.C.P. LOND., M.R.C.S. ENG., L.S.A.

A PRIMIPARA aged twenty-eight years was confined on Aug. 28th, 1895. The presentation was left occipito-posterior, and a child weighing ten pounds was delivered with forceps, the occiput not rotating and the perineum being torn to the sphincter. The labour lasted twelve hours. She recovered fairly well and progressed till the evening of the fourth day, when her temperature rose to 103° F. and she had a shivering fit; but after a copious motion—the bowels had not been open since the confinement—the temperature became normal, and she went on without regaining strength till Sept. 11th, when the temperature rose to 101° in the evening. On Sept. 12th she was carried to a sofa, but soon asked to go back again. On Sept. 13th she was not well enough to be moved. On Sept. 14th, seventeen days after labour, she had a slight rigor in the morning, followed by a more severe one in the afternoon, when the temperature rose to 104°. On Sept. 15th her temperature was 104°, the pulse 130 and very feeble. The abdomen was somewhat distended and tympanitic, the tongue being fairly clean. There was no uterine tenderness. After a copious evacuation of the bowels her temperature fell, and she remained very exhausted and feeble, but with a normal temperature till the evening of Sept. 17th, when it rose to 103° and her pulse to 120. There were no local symptoms whatever, and the distension of the abdomen had disappeared, but her pulse was so bad and her general condition so very much worse that I gave her 40 c.c. of the antitoxin at once. In six hours her temperature had fallen to 100°, and the pulse to 112, and she said her head felt much clearer; but fourteen hours after the first injection her temperature had risen to 102°, and the pulse to 120, and I then gave her 45 c.c. of antitoxin. Her temperature reached 99° in six hours, and in twenty-four hours was normal, and since then there has been constant improvement, though she remained so exhausted that it was seven weeks before she was able to walk across the room alone, and she is as thin as a convalescent from typhoid fever. The child was of course weaned before the first injection. My idea of the case is that there was a septic thrombus in a vein, which was loosened and carried into the general circulation when she was taken out of bed; but the actual cause of the symptoms is very obscure, though no one seeing her would have doubted its being septic.

Being the first time that streptococcus antitoxin has been used in England the case seemed worth publishing, and I am indebted to Dr. Ruffer for his kindness in getting me the antitoxin.

Plaistow.

A CASE OF COMPLETE SEPARATION OF THE UPPER JAW.

By G. HERBERT HOPKINS, F.R.C.S. ENG., SURGEON TO THE SWANSEA GENERAL HOSPITAL.

A MAN aged forty-nine years was admitted to Swansea Hospital on Aug. 7th, 1895. He had been struck on the back of the head by a wooden beam and knocked forward on to a coal truck, the sharp edge of which had caught him at the root of the nose. On examination the whole of the upper jaw was found to be detached from the skull, the nasal processes of the superior maxillary bones and the zygomatic processes of the malar bones being fractured. There was over an inch of separation in the middle line. The frontal sinus and anterior ethmoidal cells were opened up. The eyes were quite uninjured. The parts were cleaned and stitched up, free drainage being provided for by the nose. A Smith's gag was used, which kept the parts in very good position. The patient wore this continuously for a fortnight. He is now quite well with the exception of slight ptosis of the right eye

LIVERPOOL ROYAL INFIRMARY.

CASE OF HYDROCEPHALUS; TREPHINING; OPENING OF THE FOURTH VENTRICLE; RECOVERY.[1]

(Under the care of Dr. GLYNN, and Mr. THELWALL THOMAS).

THIS case is a brilliant example of the good results obtained by modern surgery in a disease which has hitherto, with very few exceptions, proved fatal. It is only necessary to read the subjoined notes to understand how desperate the condition was in this patient. The methods formerly adopted by surgeons for the relief of hydrocephalus—tapping the lateral ventricles of the brain through the anterior fontanelle or after trephining when the skull had already closed—were but palliative in their effects, and death was only postponed for a time. Drainage of cerebro-spinal fluid from the spinal canal has been unsuccessfully tried, and until Mr. Parkin, following out some suggestions made by Mr. A. C. Morton, trephined a child aged four years and a half on April 4th, 1893,[2] we were without proof that the operation could be done on the living subject. It is true that this first case was unsuccessful, but great temporary relief was afforded to the patient, and when the case alluded to by Mr. Thelwall Thomas in his remarks came under treatment operation with slow drainage for eighteen days was followed by complete success. It is very evident from this brief abstract that the number of cases in which it is possible to do any good by operation is very few, for it may be taken for granted that if such came under the observation of physicians they would eagerly avail themselves of this chance of effecting a cure. The operation is only in its infancy as yet, and therefore it behoves those with any experience to give the profession the benefit of it. For the notes of this case we are indebted to Mr. Thelwall Thomas, senior surgeon to the infirmary.

The patient, a young man aged eighteen, was admitted into the Royal Infirmary, Liverpool, on March 15th, 1895, with the following history. Eighteen months previously, when a steward on an Atlantic steamer, he began to suffer from occasional attacks of severe headache and giddiness, which lasted for a few hours at a time. The pain was most marked in the back of the head. The attacks increased in severity and frequency, so that for the last six months he had hardly been free from pain. Latterly the attacks of giddiness had been so severe that he fell during them, always towards the right, although surrounding objects appeared to revolve to the left. For five minutes before an attack he felt very sick (he had only vomited once, three months previously, when an iron hook struck the back of his head and determined a fit); his head felt very hot, but he experienced a sensation of coldness and numbness in the trunk and limbs and a buzzing noise in both ears. If he closed his eyes the giddiness was not so troublesome, and he could avoid falling if he clutched at a railing or some article of furniture. When he fell he had remained on the floor as long as half an hour, conscious, but unable to rise or speak, although he understood what was said to him. Memory, sight, and hearing had been gradually failing. For six months he had suffered from insomnia, occasionally getting a few hours' sleep only to wake up with intense headache. For the last three weeks he had been afraid to leave his bed on account of the giddiness. On admission he was found to be a well-nourished thick-set youth with a very dull look and a large head twenty-five inches in circumference. His temperature was 97·6° F. and the pulse was 66. Severe headache was referred to the right occipital region; the head was tender

[1] This case formed the subject of a paper read before the Medical Institution, Liverpool, on Oct. 17th, 1895, the patient being exhibited.

[2] THE LANCET, Nov. 18th, 1893.

Digitized by Google

to percussion all over, particularly so in the frontal region. There was slight nystagmus on looking to the right; the pupils reacted well to accommodation and light, but were unequal in size, the right being 3 mm. and the left 2½ mm.; both optic discs were in a condition of marked neuritis, and the fields of vision were slightly restricted. With the left ear he could hear a watch on contact, and with the right ear at a distance of four inches (this ear had been deaf since he was eight years old, when he had scarlet fever). There was no middle-ear disease. Smell and taste were normal. On getting him out of bed to stand he reeled like a drunken man and fell towards the right; he made very wide shots at his nose with the index-finger of both hands. The plantar and knee reflexes were present, but the abdominal and cremasteric were absent. He had occasional loss of control over the bladder, but the bowels were very constipated. The respiratory and circulatory systems were normal. There was no history of tubercle or syphilis in the family, and the patient had never had gonorrhœa or syphilis. Ten grains of iodide of potassium four times a day were given, and inunctions with mercury ointment were used, supplemented by ten grains of bromide of potassium in a few days, also five grains of blue pill to overcome constipation. Morphia hypodermically in quarter-grain doses was necessary to procure sleep, and the only rest from pain was due to this drug. In the first five days he lost control of the bladder on two occasions, and on the sixteenth day after the administration of a drop of croton oil given as a purgative he passed urine and fæces involuntarily. On the seventh day the pupils were sluggish and the occipital pain more severe. Six leeches were applied over the right mastoid region with some relief, and on the nineteenth day six more were used with temporary relief, but he slowly got worse. On the twenty-sixth day (April 10th) he was much worse, the pain was continuous, and vomiting had become an occasional symptom. Mr. Thelwall Thomas saw the patient for Dr. Glynn, and he now had marked nystagmus and diplopia, with paralysis of the right fourth nerve; the veins of the scalp on the right side in the occipital region were greatly distended. He could hardly stand with his eyes open and holding on to the bed with his hands; if he closed his eyes he at once fell to the right. His temperature had been subnormal since admission; it had never once reached the normal line. He had all the classical symptoms of marked intracranial pressure, and all indications pointed to the right cerebellum and vermiform process. After consultation with Dr. Glynn it was decided to explore through the right cerebellar fossa. Knowing that symptoms indicating cerebellar disease have led to operation without any discovery of tumour (nine out of sixteen operated upon—Starr), it was decided to explore the neighbourhood of the fourth ventricle if no tumour were found. On April 17th the patient's head had been shaved, well cleansed, and covered with a carbolic towel for twenty-four hours. Chloroform was administered by Dr. Armstrong, house physician. An incision, commencing at the right mastoid process and proceeding along the superior curved line of the occipital bone and down the middle line of the neck for two inches, was rapidly made. With a few strokes of the knife and a free use of the raspatory the lower part of the occipital bone was exposed. The bleeding was terrific from the scalp and emissary veins, which appeared to be legion, coming from the lateral and occipital sinuses; these were temporarily controlled by clamp forceps and sponge pressure manipulated by Mr. T. H. Agnew, house surgeon. An inch trephine was applied to the bone about the middle of the cerebellar fossa. After a few turns, when only through the external table, the patient stopped breathing. Artificial respiration by using the left arm *à la* Silvester and compression of the right chest during expiration was carried out, and the operation hurried on. Manipulation of the right arm would have hindered the operation. As soon as the crown of bone came away the dura mater bulged to beyond the outer table, was pulseless, and looked like a button mushroom. The patient made a few attempts at natural breathing; the dura mater was at once incised, when some fluid escaped. The finger was inserted and gently insinuated under the cerebellum, but nothing abnormal was felt, although the under surface of the right lobe, the vermiform process, and a portion of the left lobe were explored; so the finger was directed towards the fourth ventricle and encountered a soft bulging which immediately gave way, and the posterior surface of the medulla was clearly felt, but the space was not at all suggestive of a cyst. On withdrawing the finger a rush of fluid took place, and the cerebellum and dura mater fell within the skull and the patient breathed freely and fully. The hæmorrhage from the above-mentioned veins ceased. It was considered certain that the partition broken down was the posterior medullary velum bounding the fourth ventricle, and that an internal hydrocephalus had been relieved. The hole in the dura mater was sutured, the vessels in the flap were ligatured, and the site of the operation was cleansed with hot 1 in 40 carbolic lotion. The piece of bone was not replaced on account of a slight oozing of clear fluid which trickled through the dura mater. Silkworm-gut sutures united the flap and a small rubber drainage-tube was laid through from end to end at the base of the flap, but not into the cranial cavity. Dressings of cyanide gauze under wood-wool tissue were applied under a capelline bandage. The patient was collapsed from loss of blood, but quickly rallied, and on regaining consciousness at once cried out that the headache had gone. He slept well. The wound was dressed on the second day, and on the fourth the tube was removed. Union had taken place all along the line except, of course, where the small orifices occupied by the tube were. The ataxia as tested on the arms appeared less marked and his vision was only blurred, and he instinctively covered the right eye "to do away with the shadow," as he expressed it. The stitches were removed on the tenth day and a collodion dressing applied as a protective. There was occasional nystagmus for some days, but this and the blurred vision quickly righted themselves. For four days (from the twenty-fourth to the twenty-seventh after operation) his urine had to be drawn off and constipation required purgatives; it was also noticed that he had some weakness in the right arm and hand—dynamometer test, right, 20; left, 50; but in eight days this recovered and the test recorded—right, 75; left, 65. He was allowed to get up on the forty-first day, and on the sixty-third he was sent to the convalescent home at Woolton, walking well without ataxia, seeing plainly, and expressing himself as quite cured. During convalescence he had a slight frontal headache one day for a few hours, but he slept well and did not require a single dose of morphia or sleeping draught after the operation. On Oct. 17th he walked well without ataxia, his reflexes were normal, and he read $\frac{2}{36}$ with both eyes. The right optic disc was normal, but the left had a small patch of neuritis still present where a vessel left it. Hearing was normal in the left ear, but he only heard a watch a few inches from the right ear (this had been so for years). There was no headache or giddiness.

Remarks by Mr. THOMAS.—Obliteration of the foramina in the posterior medullary velum has been noticed in many cases of hydrocephalus, and it is just conceivable that some mild chronic meningitis may have effected this here, producing all the symptoms of intracranial pressure. Lowson of Hull[3] opened the fourth ventricle in a child and drained externally, but the case terminated fatally; the operation was performed after lumbar incision into the subdural space had failed, thus emphasising the fact that the foramen of Majendie and the fissures in the lateral recesses of the fourth ventricle were obliterated. Parkin of Hull[4] has opened the subarachnoid space in a child aged eleven months, and drained for eighteen days with success. Waterhouse,[5] in a case under the care of Dr. W. W. Ord, drained the subarachnoid space for eighteen days in a case of tuberculous meningitis with perfect success. One cannot hope much from this procedure in hydrocephalus unless the fourth ventricle is also opened.

WEST SUSSEX, EAST HANTS, AND CHICHESTER GENERAL INFIRMARY.

A CASE OF PITYRIASIS RUBRA.

(Under the care of Mr. F. SKAIFE.)

WE published in THE LANCET of July 27th of this year (p. 207) the account of a case of this somewhat rare affection of the skin, and by means of illustrations showed the general character of the eruption. In that case the patient, who was under the care of Mr. W. Cooper of Barnstaple, was also a female, but younger (being only twenty-eight years of age), and the disease continued for three and a half months without any complication; there was, however, considerable

Digitized by Google

exhaustion and loss of strength afterwards. The occurrence of the diarrhœa and the renal inflammation during the progress of this case were probably indications of the extent to which the function of the skin was interfered with, and it is interesting to observe their sequence. According to Hebra the sufferer from pityriasis rubra (acute general exfoliative dermatitis) remains in good health for a long time, but ultimately wastes, becomes cachectic, and sinks from exhaustion. For the notes of this case we are indebted to Dr. A. W. Kirkpatrick-Picard, house surgeon.

The patient, a widow aged fifty-nine years, was admitted into the infirmary on Nov. 13th, 1894, under the care of Mr. F. Skaife, suffering from a varicose ulcer on the left leg. The ulcer was unhealthy-looking, about the size of a five-shilling piece, and the skin around was eczematous. She was in a feeble state of health generally and looked considerably more than her age. Her past history was good except for occasional slight attacks of eczema. She had suffered more or less from the ulcer on her leg for some years. Apart from this the woman was apparently sound all over. The urine was normal, though of rather low specific gravity (1010). During the first ten days the ulcer steadily improved with rest in bed and treatment, which consisted of boracic fomentations for three days until it was clean, and then a weak sulphate of zinc lotion was applied. On the 24th the eczematous skin around the ulcer became markedly reddened. This condition rapidly spread over the whole body, other patches of redness occurring and coalescing until all the limbs, the trunk, and the head were affected within thirty-six hours of the time the change was first noticed on the leg. During the onset there were no marked symptoms beyond some slight prostration, and the patient was somewhat alarmed at her sudden change of colour, which became uniformly bright scarlet. There was no papular affection of the hair follicles. The condition of the ulcer was unaffected by the general dermatitis. There was no exudation or thickening of the skin, nor was there at first any itching. The mucous membrane of the mouth and throat did not show any marked congestion. The urine remained unaltered, and there was no rise of temperature and no acceleration of the pulse or respiration. The skin became covered with thin wafery scales, and this was followed by profuse shedding, large flakes coming off the hands and feet. The skin beneath the scales was bright scarlet. The patient, who had been in bed ever since admission, was kept warmly clothed and put on a light nourishing diet. Externally ointment of tar with vaseline was applied to the skin, and internally a mixture containing strychnine and digitalis was given. The condition remained without any improvement for about a fortnight, when there was a slight diminution in the amount of scales shed as measured by the handfuls removed from the bed. The front of the trunk and the head were the first parts to show areas of healthy skin three weeks after the onset; the limbs and the back were still very acutely affected. At this time (Dec. 15th) the patient was first ordered brandy, three ounces in the twenty-four hours, owing to increasing feebleness of the heart's action. The improvement in the skin of the trunk was not constant, fresh patches continually lighting up, accompanied by free shedding, though the head was never so markedly affected as at the first onset. At the beginning of January, 1895, the itching, which previously had been very slight and occasional, became very marked, especially in the legs and hands, and no relief was obtained until a lotion of subacetate of lead and opium was applied. At this time the tar ointment was replaced by a lotion of oxide of zinc, boracic acid powder, and subnitrate of bismuth in olive oil. During the early part of January the trunk and upper arms were distinctly better, the lower limbs and buttocks, the hands, and the forearms being the parts chiefly affected; these, however, slowly improved until about the middle of February, when the skin was healthy except over the buttocks, and on March 1st the skin was sound all over. The return to a healthy condition only lasted one week, for on March 8th the whole skin again became involved, fresh scarlet patches appearing almost simultaneously over the whole body and involving the entire surface within two days of its reappearance. Free shedding of the skin followed, lasting for eight days before there was any apparent diminution in the quantity of scales cast off. There was now a steady improvement with occasional slight outbursts, especially of the skin on the front of the abdomen, until the end of April. During this relapse the patient complained of marked general tenderness. The total duration of the second attack was about nine weeks, the first attack having been over twelve weeks. On March 17th, just when the diminution in the amount of shedding was noticed, there was an attack of diarrhœa which lasted until the 20th. On the 21st, for the first time since her admission, the temperature rose to 101°F. in the morning and to 101·2° in the evening, and on that day the urine was scanty and smoky, acid, and of specific gravity 1010, and it contained blood and one-fourth albumin. The temperature reached 101·2° in the evenings of the 22nd and 23rd, and on the latter date the patient complained of pain in the left knee. The joint was swollen and tender, and the synovial membrane was distended with fluid; the skin was of a dusky-red colour and felt hotter than that of the opposite knee. A back splint was applied, and a mixture containing bicarbonate of soda, carbonate of lithium, and colchicum was given. It was found necessary to remove the splint after a couple of days owing to its causing slight irritation of the skin, and the limb was steadied between sandbags. The pain had disappeared on the 25th, but the joint still remained swollen. The blood and albumin in the urine diminished steadily after three days from their first appearance, and by the 29th the urine was normal. The swelling of the knee did not entirely subside until the beginning of May. The patient was very feeble on her legs for some time afterwards, and was not able to get up until May 15th, when she was assisted into a chair. On the 30th she was carried out into the grounds for the first time. She recovered strength very slowly and was not discharged till the end of July, when she left completely cured though still somewhat feeble. During the last three months of her stay in the infirmary there was no return of her skin affection.

The satisfactory result of the case was in the opinion of Mr. Skaife largely due to the careful way in which the patient was nursed throughout her long stay of eight months and a half in the infirmary.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

Intestinal Resection and Exclusion.

AN ordinary meeting of this society was held on Oct. 28th, the President, Sir JAMES CRICHTON BROWNE, being in the chair.

Mr. C. B. KEETLEY related three cases of Intestinal Resection and Intestinal Exclusion. The first was in a girl aged seventeen, who had been ill for a year after exposure to cold and wet. She was in a hectic state and passed pus per anum. A large abscess was present in the lower abdominal wall. This was opened and the wound afterwards partly closed, the lower part, from which a fistula led to the rectum, being packed with gauze. A fistula opened into the small intestine a few days afterwards. Later, laparotomy was performed and the small intestine proximal to the fistula divided and united end to end by Maunsell's method to the gut distal to the fistula. Thus a portion of ileum was excluded, and from this portion fistulæ led to the rectum and skin respectively. The patient was now in good health and wore a colotomy truss over the fistulous opening in the abdominal wall. The second case was a girl aged fifteen, who presented two tumours in the abdomen below and to the right of the umbilicus; the lower tumour was fixed and the upper one movable. The patient was emaciated and suffered from vomiting, and there was hæmorrhage from the rectum. An incision was made over the upper swelling, the ascending colon presented, and a tumour was felt within it. The colon was opened and the tumour found to be a growth involving the region of the ileo-cæcal valve, which was intussuscepted into the cæcum. The tumour was cut off flush with the wall of the cæcum and the cut edges of the small intestine united to those of the cæcum by Maunsell's method, save that the stitches did not traverse the peritoneal coat. Six weeks later an attempt was made to remove the lower swelling, which proved to be a retro-peritoneal glandular mass, and which had grown in the interval. In taking this mass out the meso-colon was divided, and this led to the sloughing of a portion of the

Digitized by Google

wall of the colon and the formation of a fistula. The patient ultimately died from chronic obstruction due to recurrence of growth in the retro-peritoneal glands. The third case occurred in a middle-aged man who was very anæmic from advanced cancer cachexia; there was a large perfectly movable tumour in the left side of the abdomen. The growth was removed, together with the splenic flexure and a portion of small intestine which were embedded in it, the operation taking three hours and a half. The proximal portions of both colon and small intestine were united to their respective distal ends and the abdominal incision closed. The patient, who suffered great pain, died after twenty-four hours.

Mr. HERBERT ALLINGHAM related a series of cases of Intestinal Resection including all the cases he had done, as by so doing only was it possible to arrive at a definite conclusion as to the correct way of treating cases of intestinal stricture. He had operated upon 10 cases—6 recovered and 4 died. In 4 of the cases that recovered the intestines were empty prior to the resection. In the 4 that died the stricture was resected while the intestines were distended. From this it was seen that distension of the intestines at the time of resection enormously increased the risk of the operation. The following was, perhaps, the explanation: when the intestines were distended large quantities of fæces were pressed down towards the seat of union, and no doubt were constantly disturbing it by the peristalsis they set up. Further, the patient was in a way poisoned by the fæcal accumulation, and when in such a state the union between the divided ends of the intestine might be delayed or take place in a feeble or even imperfect manner. Again, in large intestine cases fæces might block the bobbin and so tear it away. Therefore, stricture of the large intestine must not be resected when the intestine above the stricture was distended with fæces. Stricture of the small intestine might be resected even when the gut was distended, for the fæces were liquid. The following course should be carried out in distended cases. The gut just above the stricture should be fixed to the abdominal wall—in fact, a colotomy performed—and so the intestine thoroughly emptied. Later the colotomy opening and stricture should be resected, and an end-to-end anastomosis done. In some cases it was possible to bring the strictured piece out through the abdominal wall; then it should be fixed and the gut above it opened. Later the strictured piece of gut could be resected, and then an end-to-end anastomosis done. Some form of button or bobbin was necessary in cases of intestinal resection or anastomosis.

The PRESIDENT expressed his admiration of these operations, which involved great foresight, manual dexterity, and ingenious contrivance.

Mr. MAYO ROBSON sent a written communication, in the course of which he stated that he had employed decalcified bone bobbins in a large number of cases. These were made in various sizes, and for them he claimed the following advantages. They enabled the operation to be completed with simplicity, rapidity, and efficiency, a continuous suture being employed and none other being required; there was no tension on the gut, and therefore no sloughing; there was a continuous mucous channel, and therefore no cicatricial contraction; the bobbin guarded the line of suture while the raised ends of it kept it in place. There was no foreign body within the gut, as the decalcified bone speedily dissolved; it was so light that the gut could not kink from its weight; its presence caused no irritation within the gut; it served equally well for all kinds of operations upon the intestine, and in the hands of himself and others it had proved safe and efficient.

Mr. L. BIDWELL spoke in favour of Halstead's method of suture, the essential principle of which was that the submucous coat should be included in every stitch. If a straight needle were used and it were pushed in until resistance were felt and then lateralised this would be accomplished. After using Maunsell's method on one occasion he had some fæcal discharge from the wound.

Mr. BRUCE CLARKE thought that no general rule could be laid down for intestinal suture, but he preferred as a rule to do without mechanical apparatus. He referred to the case of irreducible hernia in a boy (already published in the Clinical Society's Transactions), in which he resected portions of both the small and large intestine, uniting first the mucous membrane with a continuous suture and then uniting the peritoneal and muscular coats by a second continuous suture, fastening it off in four or five places round the circumference, another row being placed beyond this if necessary. He had employed the same method in gastro-enterostomy. He knew of two cases in which Murphy's button had been used in which death resulted afterwards from perforation when the button had moved down the bowel and had become impacted there.

Mr. LOCKWOOD said that two very clear theses were before the meeting. One was that the operation should not be performed when the gut was distended and paralysed, an endeavour being first made to empty the gut and then afterwards to suture. The other thesis was to use a bobbin in intestinal suture. He had operated on two cases in which the small intestine was the seat of trouble: one was a case of gangrenous gut, and it recovered; the other was one of intussusception, and it died. In both the gut was united without bobbin by a method similar to that described by Mr. Clarke. He thought that in the small intestine bobbins were not required, but in the large gut they might be wanted; the large intestine would tolerate the presence of a hard mechanical object better than the small bowel. In cases of end-to-end suture for gangrenous bowel the operation was performed under more adverse conditions than the cases Mr. Allingham had related, but the results appeared to have been equally successful. He regretted that Mr. Robson had not given a list of his cases, as a definite series of corresponding cases was required to decide as to the best method.

Mr. JONATHAN HUTCHINSON, jun., said that three years ago he resected five inches of gangrenous small intestine in a case of femoral hernia, using the simple method of suture without bobbin; that case was at present well. Three other similar cases all proved fatal: one died from giving way of the sutures soon after the operation; in that case the gut was excessively thin; the other two lived ten days and fourteen days respectively, and the fourth he thought would have recovered but for the supervention of pneumonia; during the coughing which accompanied this a small part gave way.

Mr. STANMORE BISHOP said that Murphy's button as at present made had holes which were apt to cut the intestine. Jessett's bobbin was quicker in application than Robson's. It should not be forgotten that celerity in uniting the ends of intestine was not the most important matter.

Mr. KEETLEY, in reply, said that he agreed that mere celerity was not so important as some would think. A prolonged operation would not affect the patient much if he were kept warm and loss of blood avoided. Temporary fæcal fistula seemed to have followed nearly every described kind of suture. The bobbins often acted as mechanical irritants.

Mr. ALLINGHAM, in reply, said that the bobbins kept the gut at rest and rendered suture easier. In two cases after using Murphy's button the gut had given way, and he knew that a good many other cases had occurred.

CLINICAL SOCIETY OF LONDON.

President's Introductory Address.—Impetigo Contagiosa Gyrata.—Sequel to Case of Patellar Sarcoma.—Treatment of Acute Pleural Effusion by Incision.

AN ordinary meeting of this society was held on Oct. 25th, the President, Dr. T. BUZZARD, being in the chair.

The PRESIDENT delivered an Introductory Address. After expressing his thanks for the great honour the society had conferred upon him by electing him to a post which was unsurpassed, in his estimation, by any that could fall to the lot of a practising physician, he remarked that some of the aspirations which had been expressed at the foundation of the society twenty-eight years ago had not been, perhaps, altogether fulfilled. The application of drugs and medicaments for the cure or relief of disease—the existence of which appeared to be looked upon as a foregone conclusion—overshadowed everything else in the first President's address, which contained no hint of investigation of disease with a view to its prevention as work to engage the attention of the society. The last quarter of a century had wrought an extraordinary change—a signal illustration of which was to be found in the revolution brought about as a result of Pasteur's immortal researches extended and applied to surgery by the genius of Lister. The success in the treatment of myxœdema—a disease the investigation of which was so largely

Digitized by Google

identified with the Clinical Society—was an example of the application of the scientific method in medicine as striking as anything to be found in the domain of physics. The success in the treatment of vast numbers of cases of paralysis and convulsive disorders which had followed the discovery of their frequent dependence upon syphilis was another example of scientific therapeutics as contrasted with the tentative application of drugs which was formerly the rule. And so also was the recognition of the influence of alcohol in the causation of a form of progressive paralysis, which opened the way at once to success in treating such cases. With our present knowledge of that which was formerly most frequently unsuspected we could picture to ourselves the numerous cases of this description which even at the time of the society's formation must have gone steadily on to death uninfluenced in any degree by the various drugs and other measures which were employed. How little would here avail the most careful trial and comparison and statistics of the effect of this or that drug. In the absence of the key to the cause of the disease success in treating it would be impossible. Reference was made to the question of the causation of disease by micro-organisms, and it was remarked that in disease of the nervous system the infective origin of leprosy, tetanus, hydrophobia, and diphtheritic paralysis admitted of no reasonable doubt. He suggested that there was a most interesting field for inquiry as to the possible dependence of many chronic diseases of the nervous system upon a source of infection. Infantile paralysis (acute anterior poliomyelitis), there could be little or no doubt from the occurrence of many epidemics of the disease, was an infective disorder. It was possible, he thought, that the form of progressive muscular atrophy in which the lesion occupied the same anatomical position would be likewise found to be of infective origin. Insular cerebro-spinal sclerosis, there were strong reasons for believing, owed its origin to some influence of this description. The suggestion that chorea and some forms of epilepsy had an analogous origin was yet but a conjecture, which appeared, however, to be worthy of investigation. As regarded such "family" diseases as certain myopathies and the so-called Friedreich's ataxy, the supposed hereditary element might prove, he thought, to be open to a similar doubt to that which many of us experienced respecting tuberculosis and cancer, and that what appeared to be an inheritance might be, at least in great part, the result of exposure of members of the same family to a local source of infection. The subject was one which must be approached from several sides, especially the clinical, bacteriological, and chemical. He could imagine no more important inquiry and no society the members of which were so well qualified to do justice to it as that which he had the honour to address.—A vote of thanks to the President for his able address was proposed by Mr. CHRISTOPHER HEATH, seconded by Dr. RADCLIFFE CROCKER, and carried unanimously.

Dr. RADCLIFFE CROCKER related the details of a case of Impetigo Contagiosa Gyrata. He said that the eruption was a new form of impetigo contagiosa in this country which had occurred in the last two years, and that well-marked cases were rare. It was characterised by the formation first of a pink papule the size of a hempseed with a slight indication of vesiculation at the apex; this enlarged and formed first a tense and later a flaccid bulla from a quarter to a third of an inch in diameter, with sero-purulent contents; a faint narrow red areola surrounded the bulla. The bulla dried into a thin scab, enlarging at the periphery, where there were still indications of fluid, and beyond that again the areola had become pronounced. When the centre cleared a thin greenish crust on the ragged inner edge enclosed the clear centre and was itself surrounded by a red areola. The largest single lesions were about an inch across, but some of them coalesced and formed compound lesions of several square inches in area, and a patch with a gyrated outline was thus produced. In the patient the whole back was covered with these gyrate patches, but in many patients there were only a few lesions from unruptured bullæ; pure cultures of staphylococcus pyogenes aureus were obtained, and in some cases an ordinary form of impetigo contagiosus was present simultaneously with the gyrate eruption either in the patient or in some other member of the family. He was not aware that this form of eruption had been previously recognised except by Dr. Patrick Manson, who had described a pemphigus contagiosus tropicus, and, judging from Dr. Manson's description, this other affection above discussed appeared to be identical.—The PRESIDENT asked if any plan of diagnosis could be suggested other than the bacteriological one to discriminate between this disease and pemphigus associated with disease of the nervous system.—Dr. P. MANSON, referring to the Chinese or Malay disease, said that that affection did not correspond to the one that had been shown. It was not characterised by such a degree of surrounding inflammation, there was more marked exfoliation of skin around the spots, and the eruption was entirely confined to the hot portion of the year. The application of perchloride solution of the strength of 1 in 1000, and dusting with boric acid powder, was followed by a rapid subsidence of the disease. He had ascertained on microscopical examination that the organism was a diplococcus and not a staphylococcus.—Dr. CROCKER, in reply, said that in these cases the mode of development was different from cases of pemphigus, and the eruption was scattered and accidentally distributed. It did not come out in crops as in pemphigus, and the bullæ did not remain tense. The degree of surrounding inflammation varied very much in different parts, and there was no doubt that many different pathogenic agents might produce morphologically similar eruptions.

Mr. R. W. PARKER communicated the sequel to a case of Removal of the Right Patella for Primary Sarcoma. The patient, a girl aged thirteen years, was shown to the society after the operation nearly seven years ago, as recorded in the Transactions, vol. xx., p. 254. The growth was intimately connected with the patella, which was removed. The girl recovered with a stiff joint and remained well for three years. Then a slight local recurrence took place in the scar, which was excised, after which the girl remained well for a further period of three years. Then some new growth occurred in the lymphatic glands deep in the pelvis. An attempt was made to remove them, but was only partially successful. The girl died after some weeks from exhaustion. At the necropsy masses of glandular new growth were found deeply seated in the pelvis. There were no secondary deposits in any of the organs or in any bone. The original growth was a firm spindle-celled sarcoma.—Mr. MARSH remarked on the rarity of this affection. He had only seen one case at St. Bartholomew's Hospital. The patient was a young woman; the tumour formed a large mass in front of the knee, and Sir James Paget dissected the growth entirely away. The patella was often enlarged in osteo-arthritis, but disease of that bone was rare, though he had seen a case of syphilitic disease of the patella which was at first regarded as a sarcoma. Recently he had seen a case of primary sarcoma of the synovial membrane of the knee-joint.

Dr. A. WILSON (Leytonstone) read a paper on the Treatment of Acute Pleural Effusion by Incision. The experience of three successful cases was given in favour of free incision into the pleural cavity with drainage as soon as the effusion was so large that it would not be reabsorbed. It was urged that in empyema the lung might be bound down by adhesions and compressed so as to be unable to expand again, and a case was quoted to illustrate this. The same occurred in a minor degree in pleural effusion if drainage were delayed. A case reported by Dr. Morrison[1] illustrated this. The first and second cases of pleural effusion were simple and recovered in about ten days; the effusion was large. In the second case Dr. Wilson removed five pints, the apex beat being displaced outwards to the nipple line. The heart returned to its normal position, and the lung expanded within half an hour, without distress or shock to the patient. Friction sounds indicated effusion of lymph on the pleural surfaces. On the third day the pleural cavity was shut off by the lung; then it was found that some air and fluid were sealed up lower down, so the pleural adhesions were detached to allow of drainage. Two days after the operation there were no abnormal physical signs. This was eleven years ago, and the patient died two years afterwards, the result of an accident; meanwhile she was healthy. The third case, in May, 1894, in a young woman, was complicated with severe influenza and pneumonia. When the operation was done the patient was almost moribund, being kept alive by constant oxygen inhalations and strychnine injections. Within forty-eight hours the lung had completely expanded. On the fourth day the lung closed the wound; about six pints of fluid had been removed from the right side. A week later she was very ill from pneumonia on the opposite (left) side. A fortnight later the

[1] Brit. Med. Jour., July 13th, 1895.

Digitized by Google

right side was normal. For some weeks the temperature kept rising at night, and she seemed to be in a rapid decline, so she went to Margate, where she regained the power of walking. In August Dr. Nichol reopened the incision, and about four ounces of sweet pus escaped; possibly the lung had closed the wound too soon, hence the great importance of always detaching the lung and draining the lower part. The incision was between the ninth and tenth ribs in the post-axillary line. Five months after the operation the cavity would hold from four ounces to five ounces of fluid and radiated about two inches all round the wound. The temperature kept up, and the case looked very unfavourable, like general tuberculosis. It was found that drainage was imperfect, that always about two ounces of pus were retained, and by inserting a small india-rubber drainage-tube downwards this part was kept empty. Then the temperature at once fell to normal and kept so, until finally the cavity was closed, and the wound healed in January, 1895, nine months after the operation.—Dr. S. WEST said that it was difficult to see why incision was practised when aspiration gave such good results. Incision was justifiable when ordinary methods had been tried, but had not succeeded. The lung expanded freely after paracentesis. He published recently a remarkable case treated ultimately by incision, and in that case, although the effusion was of two years' standing, the lung was not in any way bound down or adherent, though recovery was long delayed by empyema, which followed incision in spite of antiseptic precautions.—Mr. MARSH said that in cases of acute effusions into joints a surgeon would not hesitate to open and drain; similarly with acute hydrocele, acute diffuse periostitis, and with a rapid and large effusion into the abdominal cavity: these, he thought, were arguments for treating the chest in the same way.—Dr. WEST upon this wished to add a word of caution; there was much that could be done with a cavity like the abdomen that could not be done with the pleura.—Dr. WILSON, in reply, said that all the cases he had related were in a bad way, and not enough relief would have been given by aspiration. The incision relieved tension more completely than did tapping. He made the incision low down and posteriorly for the purpose of securing good drainage.

MIDLAND MEDICAL SOCIETY.

Exhibition of Cases and Specimens.

A MEETING of this society was held on Oct. 23rd at the Medical Institute, Birmingham, Dr. T. EDGAR UNDERHILL being in the chair.

Mr. GAMGEE showed a man aged twenty who had had a Thyroid Tumour half the size of a large orange, causing difficulty in breathing for the past two months. An operation was performed on Sept. 12th, 1895. Both the superior thyroid and the right inferior thyroid arteries were tied. Two small processes from the upper part of the gland and a process at the lower part into which the left inferior thyroid artery entered were left in position. Complete relief of symptoms ensued.

Dr. FOXWELL showed the Lungs of a man who had died from Acute Pneumonia. The interest lay in the great thickness of the visceral pleura over the greater part of each lung. The thickening was entirely fibrous, and on the surface lay recent lymph. The parietal pleuræ were not thickened and adhered to the visceral only by slight recent inflammatory bands. The illness began with diarrhœa followed in three days by stabbing chest pains. Widespread moist friction sounds were first heard, the pneumonic signs appearing later and very gradually, and never amounting to marked dulness or intense tubular breathing. The pneumonia crept over the greater part of both lungs. The presence of friction and absence of flatness in the percussion note prevented recognition of the old thickened pleuræ. The peculiarity of the dulness and breath sounds were considered as probably due to the partial distension of both chest wall and lung owing to the restraining pleura. The cause of the thickening was doubtful. There was no history of alcohol or syphilis. As a child the patient had had rheumatic fever twice; the heart was, however, healthy. Still, one or both attacks may have been complicated by pleuro-pneumonia, with the resulting slow fibroid growth resembling scar tissue. The case showed well the great difficulty sometimes arising in the diagnosis of thickened pleura in acute pneumonia, and, therefore, the great value of a knowledge of the previous state of a patient in making a prognosis.

Dr. SHORT showed a portion of Intestine from a case of Enteric Fever. The Peyer's patches were unusually large, with deep and extensive ulceration. Tremor of the hands had been a marked symptom throughout. Towards the end of the third week of her illness the girl, who was subject to epilepsy, had a severe fit. After this the pulse rapidly failed, and she died in about twenty-four hours.

Dr. SHORT also showed the Liver, Stomach, and Pancreas from a woman aged sixty-four. The stomach was divided into two cavities by an indurated cicatricial band which appeared to be secondary to a large transverse ulceration. There were several large nodules in the pancreas and neighbouring glands, strongly suggesting a malignant origin. The liver showed a large abscess towards the posterior part and several smaller ones in various parts of the gland; whilst scattered all over it were numerous soft hæmorrhagic foci obviously rapidly breaking down. Nothing was found elsewhere to suggest a pyæmic origin. The marked feature of the case was the latency of the symptoms up to a few days before death.

Mr. MARRIS showed a specimen of Intra-pericardial Aneurysm of the Aorta, with chronic adhesive pericarditis.

Mr. HEATON showed a Growth removed from the Umbilicus of a Boy aged four years and a half. The child was brought with a history that when he strained he "passed water from his navel." On making him cry a small jet of a clear yellow fluid ran from the umbilicus. A fine probe passed into a fistula at the umbilicus downwards and backwards for three inches and a half. The fluid was clear, light yellow, had a peculiar soapy feel, and was strongly alkaline—in fact, chemically resembled succus entericus. On abdominal section being performed a large, thick-walled, pear-shaped sac was found passing downwards and backwards and adherent by a band of fibrous tissue to the small intestine. The sac was partially excised in September, 1893. In August, 1895, the remaining part of the sac was removed and showed on microscopic examination the structure of small intestine. The vitello-intestinal duct forming the direct communication between the intestines and the yolk sac had been only partially obliterated. The end nearest the intestine was represented by a fibrous cord. Its outer half opened at the umbilicus and became distended by secretion into a thick-walled muscular sac.

Mr. CHAVASSE read notes of a case and exhibited a male adult upon whom a Primary Amputation of the Entire Upper Extremity had been performed for a machinery accident in May last. After the initial shock had been overcome recovery was rapid and healing complete in a month.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

President's Address.—Symphysiotomy.—Splenic Leukæmia following a Blow upon the Abdomen.—The Relation of Influenza to Diseases incidental to the Seasons.—Excision of the Larynx.—Exhibition of Specimens and Cases.

A MEETING of this society was held on Oct. 18th, Mr. A. W. MAYO ROBSON, President, being in the chair.

The PRESIDENT delivered an address, which we print in full this week, on the Surgery of To-day as compared with that of Twenty-five Years Ago, illustrated by the Work in the General Infirmary at Leeds.

Dr. BRAITHWAITE read the notes of a case in which he had performed Symphysiotomy.

Dr. CHURTON showed a case of Splenic Leukæmia following a Blow upon the Abdomen. The patient was a man aged twenty-eight years whose spleen filled the greater part of the left abdomen and extended beyond the middle line. The red blood cells were diminished in number; the leucocytes were 1 in 10. The patient looked well. The face and lips were red, the eyes bright, and the movements brisk; but he was unfit for heavy work (tachypnœa). His family was healthy. He had had no illness until this, though he had been careless in his diet, and had lived in a very damp house, and was often wet at work. In 1887 he was kicked in the abdomen rather severely, but not disabled. In 1892 a piece of steel weighing 2 lb. flew off a mass of steel struck by a hammer of 85 tons impact, and, travelling in an upward direction from two feet above the ground, struck him at eight yards' distance on the left abdomen about two inches from the

Digitized by Google

median line and just above the umbilical horizontal line. The shock might thus have been directed through the colon and spleen, injuring both. He fell violently, but resumed work after three hours. The skin was deeply bruised for two or three weeks; the diameter of the bruise was about three inches. Eight or nine months after the blow he began to feel weak; three months later the spleen was found to be enlarged. Gradually quickness of breathing came on. He left his work in March last. When first discovered two years ago the spleen was about half its present size; probably, therefore, it had taken one year to attain that size. It seemed possible that after the blow micro-organisms from within had traversed the damaged intestine and invaded the similarly damaged spleen.

Dr. BAMPTON (Ilkley), in a paper on the Relation of Influenza to Diseases incidental to the Seasons, submitted the following propositions:—1. That we recognise a pure type of influenza. 2. That we meet with influenza *plus* the disease peculiar to the time of the year—e.g., influenza *plus* bronchitis, influenza *plus* follicular tonsillitis, or *plus* summer diarrhœa. We have then to deal with compound diseases. 3. We may meet with two specific epidemic diseases running concurrently—e.g., mumps and influenza. We then have to deal with a dual disease, each modifying the other. 4. We recognise the lowering of the resisting power during an attack of influenza, bringing into evidence the disease diathetic to the individual and *vice versâ*. 5. The modern explanation of the classic clinical saying "that in times of epidemics all diseases are apt to assume an asthenic type" is that at such times we have the specific epidemic germ grafted on to the ordinary disease.—The paper was discussed by Dr. BARRS, Dr. DE MOUILLOT, Mr. WOODCOCK, and Dr. CHADWICK.

Mr. WARD read a paper on Excision of the Larynx, illustrated by cases in which he had performed the operation.

The following card specimens and cases were exhibited:—

Dr. ADOLPH BRONNER (Bradford): Lower Turbinated Bones removed for Nasal Obstruction.

Dr. TREVELYAN: A Becker's Microtome.

Dr. BARRS: Spastic Paraplegia; Pseudo-hypertrophic Paralysis; Athetosis.

The PRESIDENT: Case of Gastrotomy with Sphincter formed by the Rectus Muscle; Myomata Uteri removed per vaginam; Multiple Fibroids removed by Abdominal Hysterectomy, with a new treatment of the Pedicle.

Mr. LITTLEWOOD showed a man aged sixty-nine on whom he had performed Supra-pubic Prostatectomy on Aug. 22nd, 1895, removing eleven drachms of prostate. The patient had complete retention with foul urine before the operation; now the urine is clear and is passed every three or four hours during the day and once or twice during the night.—Mr. LITTLEWOOD also showed a specimen of Malignant Disease of the Cervix Uteri removed by Vaginal Hysterectomy. The broad ligaments were very wide, as there was a hydro-salpinx on one side and a small ovarian cyst on the other. These were removed, the patient making a good recovery.

Reviews and Notices of Books.

From Matter to Mind. By MARCUS R. P. DORMAN, M.A., M.B. Camb. London: Kegan Paul, Trench, Trübner, and Co. Pp. 319. 1895. Price 7*s.* 6*d.*

THE origin of mind and its relation to matter have been subjects of discussion from very early times, and the answer of the latest writer whose book now lies before us supplies little information that is in advance of the common knowledge of the day. The author commences by accepting as most probable the theory of Kant that space was occupied originally with countless meteorites, which, attracted by force of gravity to certain centres, formed suns, generating intense heat by the violence of their mutual impact. The fundamental material, or, as the Germans term it, the "Anlage," of such suns we still may see in the nebulæ. When formed a cooling process, by radiation into space, takes place, which will ultimately lead to their extinction. The planets have been formed in the same manner. What led to the first movement of these distributed meteorites? "Gravity," he says, "originally gave rise to heat, and it is extremely probable that heat has since become differentiated, according to Nature's requirements, into all the other forces with which we are acquainted. It has an intimate relationship to light, electricity, mechanical forces, and chemical action, which are all essential to life. It is thus possible, then, that the great force, life itself, at some very remote period was derived from the same source." Why, we may ask, should it have been at some very remote period? Why not to-day?

It is, indeed, in a high degree improbable that life began when the temperature of the world was high. It is far more probable that it commenced at such temperatures as are those now common in the warmer parts of the earth, and at which the lower forms of organic life still live and thrive and multiply best. But we look in vain for any explanation, or even suggestion, of the origin of life—of the essential difference between the living and the not-living combination of atoms which the title of the book might reasonably lead us to anticipate. The conclusions of his second chapter are: that matter consists of elements which are constantly combining with other elements to form compounds; these in turn break up and recombine, always with manifestation of heat; that the properties of the elements are lost in the compound, but reappear when the elements are again set free: and that there is no loss of matter. He then asks, "What is the object, then, of these repeated changes in the elements? The answer is at once apparent—the manifestation of energy and the maintenance of life." So that the author accepts a purely teleological view of inorganic changes. He then proceeds to define energy, distinguishing between kinetic and potential energy, and then discusses organic matter and life. Of the nature of the latter he sums up the chapter in these words: "Living organisms are complex compounds, built up of simple elements. They are possessed with a force called life. This life is dependent upon certain conditions, of which heat, moisture, and nutrition are the chief. The organism has the power of selecting its food and throwing off what it does not require. During its life it has the power of reproducing similar organisms. The length of time the force of life remains in the organism is limited." Alas, in all this we do not find the bridge connecting living with non-living things. A great gulf still separates matter from mind.

Dr. Dorman again takes up a teleological view in regard to plants which somewhat surprises us. "But what," he remarks, "is Nature's object in creating the vegetable world at all?" and his reply is "that animals must have their protoplasm ready prepared for them." Animals no doubt primarily feed on vegetables even in the case of carnivora, and are therefore the outcome of the plant and could not exist without plants; but it is pure surmise to say it was Nature's object that animals should proceed from plants. Several chapters are occupied with a description of the animal kingdom, of the process of development, and of the gradual ascent from the lower animals to man, with incidental sections on Rudimentary Structures and the Origin of Sexes. These are all, though briefly, correctly given.

The second book, which is devoted to the development of the mind, is much the most interestingly written part of the volume. In this the author traces lightly the advances of mental manifestation, from the lower form of animal life to the higher arthropoda and vertebrata. He rightly declines to recognise the distinction so often attempted to be maintained between instinct and intellect, and he thinks the passage easy from the monkey to the man. We should have liked to have gained some insight into Dr. Dorman's ideas on the origin of instinct. Original man, he thinks, when he wanted food, either plucked berries, collected shellfish and blubber, or killed small animals,

Digitized by Google

his instinct enabling him to detect what was good to eat. But how did the instinct arise? Dr. Dorman proceeds to point out that by the accidental contact of two fluids or friction between boughs of trees fire would be discovered. Shelter being required, he would construct a rude hut. Wood floating on water would suggest it as a means of crossing rivers. The hollow trunk of a tree would be the prototype of a canoe, and the means adopted for the formation of this would lead to the invention of stone instruments. The advantages of sociability would soon be manifest; communities would be established, differentiation of work carried out, and in due course wars arise which may hereafter be settled, not by killing men, at a vast outlay, who are paid at a fixed rate to risk their lives, but by the conflict of mind with mind. The succeeding chapters deal with the further development of the mind, beginning with impressions from simple sensations and pain; reasoning from facts, in the course of which the foundations of Christianity are dealt with, and a thoroughly agnostic view taken of them. There are some sensible remarks on the early training of the intellect, in the course of which Dr. Dorman points out its immense importance. Every subject, he thinks, should be taught from a historical standpoint, and the reasoning powers should be cultivated rather than the memory. The scheme of education he proposes is, however, very large, since it includes comparative philology, history, geography, the elements of science, and the cultivation of poetry, painting, and music. We fear little time would be left for the stimulation of the imagination of the cheerful youth by the habit of "building castles in the air" which Dr. Dorman proposes if each of these were studied on the historical method. Finally, he discusses the nature of the will, and gives chapters to Ethics, Marriage, the Soul, Theosophy, Evolution and the Bible, and Faith. The range of subjects, it will be seen, is rather wide, and though many of them are ably treated within the limits the author has imposed on himself, they might be greatly expanded with advantage.

The Animal Tuberculoses and their Relation to Human Tuberculosis. By ED. NOCARD, Professor of the Alfort Veterinary College. Translated by H. SCURFIELD, M.D. Edin., D.P.H. Camb. London: Baillière, Tindall, and Cox. 1895.

DR. SCURFIELD has done good service in translating into English the little monograph on this formidable malady, written by a most active investigator, who has done more to enlighten the public of France as to the nature and dangers of the disease than anyone in that country, and who must be accepted as a leading authority upon everything pertaining to it, either from a pathological or a hygienic point of view. The subject is of great interest and the highest importance, and because of the dangers attending it in flesh- and milk-producing animals, as well as its extensive prevalence and the heavy losses it occasions, it cannot be too seriously considered and promptly dealt with. In this country, though it is now about twenty years since attention was directed, in a lengthy article that appeared in the *British and Foreign Medico-Chirurgical Review*, to the great risks this disease in bovines imposed on mankind, and though these risks have been abundantly proved to be real and constantly increasing since that time, nothing has been done to check its ravages or diminish its dangers, for the Royal Commission which was appointed some time ago added but little to our knowledge of the disease, nor did it afford much information as to how the malady is to be checked among animals. As is stated in the introduction to M. Nocard's work, there is no disease in existence which attacks so many different kinds of animals. Not one of our domestic animals is completely refractory to it, they simply vary in their susceptibility, and those which under natural conditions escape infection are unable to withstand experimental inoculation. Our poultry-yards, even, are often decimated by tuberculosis; and the tribute paid by man to it is so heavy that in Paris, according to the latest statistics, more than 23 per cent. of the deaths were due to it, and even this high percentage is exceeded in many European towns. But the disease causes the greatest amount of destruction among cattle, though the proportion varies according to the locality, for, while it may be entirely unknown in some places—though nowadays these are, indeed, few—in others it may affect from 10 to 40 or 50 per cent. of the bovine population. In this way it is the most damaging scourge among cattle, and exacts a far heavier tribute than contagious pleuro-pneumonia ever did. Next to cattle, pigs appear to be the most liable to tuberculosis, though in them it is comparatively rare, and still more infrequent in the horse, while it is scarcely ever met with in the sheep and goat—indeed, these animals are markedly refractory to experimental inoculation. Cases of dogs becoming tuberculous when brought into contact with phthisical persons have been reported, and kittens, it is asserted, are easily infected by the ingestion of tuberculous material, particularly milk.

M. Nocard says that when the disease is localised in the pleura or peritoneum, as it frequently is, the Germans and English call it "Perlsucht," or "pearl disease," because the tuberculous nodules of the serous membranes, before they become too old, bear a strong resemblance to pearls. So far as this country is concerned this is an error, as the designation of "pearl disease" is popularly unknown, the masses of tubercle in the situations mentioned receiving the name of "grapes" from the manner in which they are clustered. Hence it is by butchers and others simply called "grapes" or the "grape disease," though it has other vulgar and significant appellations.

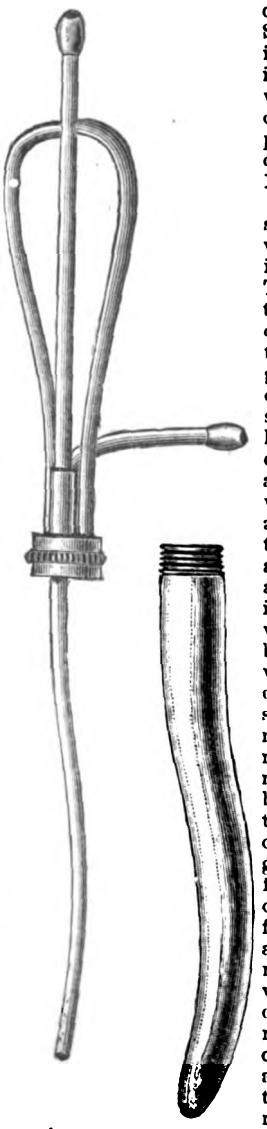
The monograph deals with tuberculosis of cattle, pigs, horses, small ruminants, dogs and cats, as well as birds, in separate chapters, and sufficiently in detail to include all important particulars with regard to the lesions, the symptoms, the clinical, bacteriological, and experimental diagnosis, and the various methods of inoculation. M. Nocard insists on the identity of the disease in man and animals, and advocates the employment of tuberculine as an unfailing guide in detecting its existence, even in cattle which give no evidence of being infected. Proof is given of the malady being both infectious and contagious, but the chief cause operating in its spread among cattle is the introduction of a diseased cow into a healthy herd, though an instance is given in which a phthisical cowman infected the cows he attended. With regard to the danger mankind incurs M. Nocard is very emphatic, and he gives cases which undoubtedly were due to accidental inoculation from tuberculous cows; to these cases might be added that of a veterinary teacher who died less than a year ago in this country from acute pulmonary phthisis, presumably due to an inoculation wound in the hand while examining the carcase of a diseased cow. Strong evidence is also adduced by the author in favour of human contamination by milk from affected animals; he therefore energetically insists on the sterilisation of all milk intended for use as food. With regard to the use as food of the flesh of tuberculous animals, he does not go so far as some hygienists, who would condemn the entire carcase of a cow if only a small tuberculous nodule were found in any part of it; he, on the contrary, would permit it to be issued as food if it were of good quality and the lesions were localised. In cases of generalised tuberculosis, however, he would exclude the entire mass from consumption, and he gives his reasons for following both courses. The entire suppression or eradication of the disease from among animals is also, of course, included in the treatise, and there can be no doubt that if the measures the author recommends were adopted and

Digitized by Google

rigidly carried out everywhere the scourge would eventually be subdued. By all who take an interest in this profoundly interesting matter M. Nocard's remarks should be read and pondered over, for tuberculosis in man and beast is certainly one of the gravest questions, if not the gravest, with which the sanitarian has now, or ever has had, to grapple. Dr. Scurfield has given an appendix of three pages in which the scheme of Professor Bang of Copenhagen, for eliminating tuberculosis from a herd of infected cattle without destroying all of them, is described.

JOURNALS AND REVIEWS.

The Journal of Anatomy and Physiology. Conducted by Sir GEORGE HUMPHRY, Sir WILLIAM TURNER, and Dr. M'KENDRICK. Vol. XXX., Part 1. October, 1895. London: Charles Griffin and Co. Price 6s.—This part contains fourteen original articles, viz. :—1. Homoplasty of the Brain of Rodents, Insectivores, and Carnivores. With a Plate. By Gustav Mann, M.D. 2. Clinical Value of the Four-root Theory of the Cranial Nerves. By T. K. Monro, M.D. 3. Optic Nerve as Part of the Central Nervous System By the same observer. 4. Origin and Intracranial Course of the Ophthalmic Artery, and the relationship they bear to the Optic Nerve. By Edward Fawcett, M.B. 5. Retinacula of Weitbrecht: What is their Function? By the same writer. 6. Lymphadenoma (Hodgkin's disease) of the Lymphatic Glands as a Distinct Pathological Affection. By Gordon Sharp, M.B. 7. Nerve of Wrisberg. By A. Birmingham, M.D. 8. Organ of Jacobson in the Monotremata. With a Plate. By R. Broom, M.B. 9. Effects upon the Testis of Ligature of the Spermatic Artery, Spermatic Veins, and of both Arteries and Veins. With a Plate. By Joseph Griffiths, M.D. 10. Critical Note on Colour Vision. By John Tennant. 11. Note on the Stereophotochromoscope: a New Optical Instrument. By David Fraser Harris, M.B. 12. External Characters and Some Parts of the Anatomy of a Beluga (Delphinopterus leucas). With a Plate. By John Struthers, M.D. 13. Morphology of the True "Limbic Lobe," Corpus Callosum, Septum Pellucidum, and Fornix. By G. Elliot Smith, M.D. 14. Anomalous Muscle of the Thorax connected with the Diaphragm. By Francis J. Shepherd, M.D.



The Journal of Mental Science. October, 1895.—The reappearance of articles by Dr. Nicolson and Dr. Maudsley, after too long an absence from the pages of the journal, renders this number specially interesting. Dr. Nicolson deals with "Crime, Criminals, and Criminal Lunatics." He raises a timely protest against some of the extravagances into which the latest school of criminologists have been betrayed. With all the weight of his authority and experience he points out on how unreal a basis many of the theoretical deductions of the criminologists rest. He objects strongly to applying to criminals generally the biological peculiarities and anomalies found in a minority of the criminal class. Dr. Maudsley, in his lucid article on "Criminal Responsibility in relation to Insanity," also devotes his attention to the subject, and in pungent and powerful satire ridicules the unripe observations and sensational theories in vogue amongst criminologists, which he states "make the judicious grieve although they make the vulgar stare." What may be termed a duel takes place between Dr. Batty Tuke and Dr. Clouston on the respective merits of rest and exercise in the treatment of mental cases. Much can be said in favour of both aspects, but probably Dr. Clouston's advocacy of judicious exercise will meet with general approval. Some interesting information regarding epilepsy is given in the psychological retrospect. The name of Dr. Rayner appears on the list of editors in place of that of the late Dr. Hack Tuke.

The Birmingham Medical Review.—This is always an [illegible] periodical. In the October number is a paper by Mr. Law Webb commenting on the Immunity from Carcinoma which he has observed among colliers. He suggests that the sanitary habits of the collier—i.e., to wash the outside of the body daily, and never to take any water, save in the form of tea or coffee, to drink—may have something to do with it. Dr. Paul Chapman contributes a useful note on the Misuse of Emollients in Chronic Superficial Inflammation.

New Inventions.

NEW AND IMPROVED FORM OF HOT-WATER UTERINE DILATOR.

THE accompanying illustrations show a new form of uterine dilator designed and used in hospital and private practice by Dr. Geo. Bell Todd of the Samaritan Hospital for Diseases of Women, Glasgow. The instrument may be used as an ordinary Hegar's dilator without the application of the hot-water arrangement. Still, the principle on which the instrument depends is that while in use it may always be kept warm by a stream of hot water circulating through it of a temperature requisite to keep the dilator heated to about 10° or 15° F. above normal.

The set of dilators comprises six graduated sizes, commencing with No. 10 catheter size, and increase in regular proportion. They are made of block tin so that they may be bent into various curves to suit special cases, are thick and stout behind, but gradually taper forwards into a conically pointed end. They all screw into and fit the same handle. The handle is constructed especially for lightness, durability, and cleanliness. It is furnished with a tube marked "inlet," which after running through the fenestrum of the handle terminates in a portion made of softer metal, and extends forwards into the interior of the hollow dilator within half an inch of its point; by this means the current of hot water is led into the interior of the dilator, and makes its exit by the short downwardly curved tube marked "outlet." By attaching a rubber tube to the outlet the water may be conveyed to a suitable vessel beneath the operating table or on the floor. The instrument can be connected with any existing irrigating apparatus such as is usually found in hospitals. The length of the handle gives the operator full command of the instrument, and no boring or awl-like movement is necessary or allowable as with the short-handled Hegar's dilator. By the aid of heat the resistance of the tissues about the cervix is more easily overcome and less force is employed in dilatation, so that there is less risk of rupturing the structures about the cervix uteri. Owing to the tapering shape of the dilators they are not so liable to be caught or gripped by the structures when they are withdrawn as when a cylindrically shaped instrument is used. Dilatation is more easily performed by the aid of heat in cases where it is unsuitable to give an anæsthetic.

Messrs. S. Maw, Son, and Thompson, 7 to 12, [illegible] street, London, are the makers of the inst[illegible]

THE LANCET.

LONDON: SATURDAY, NOVEMBER 2, 1895.

WE print in our issue this week the petition of the students of the London School of Medicine for Women to the Royal College of Physicians of London praying for admission to the examinations and diplomas of the College. This petition, as will be seen, is signed by a numerous and influential body of our profession—having, indeed, affixed to it a series of names that would make it impossible for it to be treated with other than deep consideration and respect. And in this spirit, we are glad to say, it was received by the College at the debate which ensued upon it in Comitia on Thursday, Oct. 24th, while the result of the voting must have come as a surprise to more than one Fellow of that ancient corporation. For of 109 Fellows present at the Comitia 50 were found to support the petition. A similar petition has been presented to the Royal College of Surgeons of England, and is set down for discussion in the agenda of the annual meeting of the Members and Fellows of the College on Thursday next, and its fate will be awaited with curiosity. The constitution of the two Colleges is so different that it is possible to conceive the following anomaly—that while the corporations as a whole might be of similar opinion with regard to the petition, it might be amply supported by the governing body in one place and emphatically rejected by that in another. For the Comitia of the Royal College of Physicians of London—i.e., the Fellows in conclave—is a large body, and its vote, more nearly approaching the vote of a plebiscite, would be more inclined to uphold revolutionary courses; while the Council of the Royal College of Surgeons, consisting of a much smaller number of men, much under the sway of tradition and hereditary principle, would for various reasons be more inclined to be reactionary. But before the question comes to the notice of the Council of the Royal College of Surgeons it will have been voted upon at a general meeting of the College, so that the Council will know the views of their electorate before proceeding to discuss the petition.

From every point of view, then, it would seem that the petition of the women is to receive consideration from the Colleges. The Royal College of Physicians has debated the question, and, in an assembly presumably representing the feeling of the highest grade in its corporation, has decided by a nearly equal vote not to admit women to the examinations and diplomas. The vote to be taken at the annual meeting of Fellows and Members of the Royal College of Surgeons will give the medical world an opportunity of seeing what the surgical branch of the profession at large thinks of the question; while the meeting of the Council of the same Corporation will register the views of the oligarchical government of that body. So that, whatever the issue may be and whether it be but a temporary or a permanent settlement of the question, we are glad to feel that the women are to have fair play. There are many arguments—and most of these are familiar to our readers—against the inclusion of women in our ranks. We do not, however, intend at this moment to set them out, but only to say a few words on one much employed in behalf of the petition at the recent meeting at the Royal College of Physicians. The chief argument in favour of acquiescence was that as women have obtained admission elsewhere it was illogical to refuse it to them at the College. This we have no hesitation in saying is no argument whatever. Their inclusion in other bodies is entirely beside the point. It is true that women can win the most coveted medical degree in the profession, and that they can obtain medical diplomas from several licensing boards; but this can have nothing to do with the refusal for the present of the Royal College of Physicians of London to admit them to its diplomas save that the refusal is deprived of much of its sting by the fact that it does not debar the petitioners from proceeding with the profession of their choice. The action of other corporations can only be quoted as a precedent, for or against, by displaying fully the results of the concessions to women; the fact of the concession counts for nothing at all.

And here we will leave the matter as far as the Royal College of Physicians of London is concerned. The Fellows of the College under a judicious and temperate President, with the advice of one of his wisest and most highly honoured predecessors, have decided for the present to reject the petition. They have a right to do so, and have acted from the highest desire to do their duty by the College. To some their course will seem to have been decided by a sentimental desire to hand on traditions merely—for who can imagine HEBERDEN, HALFORD, WATSON, or JENNER sitting in Comitia with women? Others will see in their action a desire to act as they consider rightly without reference to what other bodies have done: and, possibly, with some disregard of expediency. On all hands we hear that the result of the voting has been a matter of surprise. Yet the fact that at least as many are surprised at the extent of the support which the petition received as are surprised at the solidarity of the opposition, would seem to show that the result might have been foreshadowed.

THE event of the academic year is the celebration of the four-hundredth anniversary of the founding of the University of Aberdeen. By the Bull issued by Pope ALEXANDER VI. the "Studium Generale et Universitas Studii Generalis" arose in the then Ultima Thule of learning, and the provision thus made for supplying the north with education, professional and lay, has borne fruit beyond the most sanguine dreams of the social enthusiast. If, in BACON'S memorable phrase, the "Georgics of the Mind" are the fit subject-matter for academic husbandry, they have in Aberdeen given occasion to some of the finest specimens of intellectual "high-farming"—worthy, indeed, of a VIRGIL

Digitized by Google

to do them adequate justice in song. The industry and sagacity that evolved such harvests from a soil apparently unpromising and under conditions well-nigh desperate are among the most conspicuous triumphs in the roll of national "self-helps." With more than her share of the Scottish love for the liberal arts, Aberdeen from the outset showed her grasp of the educational truth that the training of the mind must precede all professional or specialised activity, and that the more finely tempered, the more vigorously braced the mental instrument, the more will its activity be profitable and nobly prolific. Hence it is that with all her so-called worship of the "knowledge that pays" she has rarely, if ever, been untrue to "knowlege for its own sake." If proof of this were wanted it would be found in the prominence she has always given to the "humanities" in general and to moral and metaphysical speculation in particular—to that kind of knowledge and culture which in spite of its lofty ideal receives but scant attention from peoples who love to call themselves practical. And, like other Scottish seats of learning similarly inclined, she has found the discipline she vouchsafed her *alumni* the best adapted even for the work-a-day walks of life. Just as, according to Sir WILLIAM HAMILTON, the trained metaphysician like DESCARTES or LEIBNITZ found the most difficult problems of the mere mathematician an "easy game," so the student, braced and developed by the *palæstra* of the Aberdonian curriculum, comes to the special studies of law or medicine prepared to grapple successfully with the details or principles of either—thanks to the well-schooled mental equipment with which, again in BACON'S phrase, he "bowed and buckled himself" to the task.

We must go a step deeper, however, in the Scottish civilisation to account for the growth, development, and yield of Aberdeen University. The conditions under which she lived and throve were not exhausted by the Papal Bull. Like every other seat of learning north of the Tweed, she owes much to the educational system of which the inspiring genius was JOHN KNOX. That mighty reformer, in other senses than the religious, grasped the *perfervidum ingenium* of his compatriots in its totality, and his requirement that "wherever there is a parish church there must be a parish school" was calculated to bring up to the universities a perennial contingent of aspirants to the higher culture. Scottish annals, literary and scientific, teem with evidence of the blessings thus conferred on all ranks of the people through generations when other countries had nothing similar to show. The professions were in this way recruited, and university education fed, from social strata which—south of the Tweed, for example—were content to supply the menial service of the *petite bourgeoisie*, and fresh and vigorous blood thus welled up from sources elsewhere practically dry. In the profession of which, more than any other, it may be said "its field is the world"—a profession owing least to locality or tradition, but capable of being practised wherever the *corpus humanum* lives and moves—this outlet for Scottish genius was appreciated from the first in Aberdeen. Medicine, having no articles or irreducible creed like divinity, not bound by statute or precedent like law—open indeed to the practitioner in whatever clime or state he chose to settle—possessed peculiar attractions for the ambitious young Scot and pre-eminently for the young Aberdonian. At nearly every Court in Europe we read of Aberdonian graduates acting as physicians; while in the services—naval, military, and diplomatic—Aberdeen has contributed surgeons, sanitary officers, and consultants out of all proportion to the number of her duly qualified sons. For two centuries and more she has recruited the profession all the world over with men of masculine ability and varied accomplishment, and in that now drawing to a close she has produced names second to none in every department of the healing art. Sir JAMES MACGRIGOR on the Army Medical Staff, Dr. NEIL ARNOTT in medical philosophy, Dr. ALEXANDER KILGOUR in clinical teaching, Dr. FRANCIS ADAMS in medical scholarship, Dr. MATTHEWS DUNCAN in gynæcology, and Sir ANDREW CLARK in consultant practice are, in Baconian language, "instantiæ prærogativæ" in their respective walks, men whom the most august of *almæ matres* might be proud to own.

And the benefits such *alumni* conferred on their University did not stop there. Many of them, in gratitude for the start in life it had given them, endowed it with substantial bequests. Earl MARISCHAL, a hundred years after the foundation of the school, added to its resources the College that goes by his name, and this foundation, after rivalling and stimulating its elder sister for 267 years, has, by Act of Parliament, been amalgamated with the original seat of learning to form the "Universitas Aberdonensis" so honourably *en évidence* to-day. Other adjuncts and subsidies to the efficiency of the school have steadily been added since Earl MARISCHAL'S time, till they have culminated in the splendid extension buildings conferred by the late Dr. CHARLES MITCHELL. Of these we have given elsewhere an adequate account and will at present only say that as conceived and carried to completion they will prove equally honourable to the grateful pupil who gave them and to the *alma mater* by whom such gratitude was inspired. But with this addition to her equipment Aberdeen would be untrue to her enterprising and vigorous past if she rested on her oars and ceased to spread her sails for new voyages of discovery or new expeditions into the scientific unknown. She has rivals, and very formidable ones, with some of whom she is too wise to compete or to do more than silently profit by. "Not wholly in the busy world nor quite beyond it" may, according to the late Mr. MARK PATTISON, be the ideal of a university's situation, and Aberdeen undoubtedly enjoys that advantage. But, as a medical school, what she gains in the peace required for purely scientific study, she loses by the absence of the seething tide of humanity which makes London, for example, the "happy hunting ground" of all clinical observation and research. Indeed, there is no medical school which can be called complete in itself. Each has, more or less, its special feature—local, accidental, or historical—which makes it unique among the fraternity. It is the praise, the high praise, of Aberdeen that,

"Pæne sub Arcturi sidere nata poli,"

she combines so much of all that contributes to make what the old Greek defined as the perfect physician, the τέλειος ἰατρός, and that amid the competition brought about by four hundred years of existence, competition fed by her

Digitized by Google

own *alumni* transferred to rival seats of learning, she will enter on the twentieth century more vigorous than at any epoch of her history and better equipped to enhance the common standard of professional culture for the honour of the British civilisation and the welfare of mankind.

THE Report of the Council of the Royal College of Surgeons of England deals with the usual variety of topics. It is compounded of the Secretary's report published in the Calendar of the College, reports from the Curator and Librarian, abstracts of the lectures delivered during the past year, together with the returns of the results of professional examinations, a statement of receipts and expenditure (both of these tables being found in the Calendar), and an obituary. With the obituary less trouble has been taken than in preceding years, the names of deceased Fellows only being given, whilst the Members are dismissed with the brief statement that the names of 354 Members have been removed from the Calendar in consequence of death, several of them having died some years ago. As the obituary is omitted from the Calendar it appears to us to be a pity that it should be lopped of its proper proportions, and we trust that next year the names of the deceased Members as well as of the deceased Fellows will be published in the Report as heretofore.

During the year new by-laws dealing with the election and admission of members of the Council, the misconduct of Fellows and Members, and the fees for the certificate in dental surgery have been obtained. The new by-law (Section 4), which simplified the mode of distribution and return of voting papers for the election of members of the Council, came into force before the last election and resulted in a considerable increase in the number of votes recorded by the Fellows. The original form propcsed by the Council for the new by-law (Section 16) relating to the misconduct of Fellows and Members was couched in phraseology which appeared to Mr. ASQUITH, the then Home Secretary, to be open to some objection on the ground of its wide and indefinite character. Mr. ASQUITH had been addressed by the Society of Members, who strongly objected to any fresh powers being conferred on the Council of the College, adducing in support of their objection the unrepresentative character of the Council, the manner in which the Council had hitherto treated the Members, the nature of the by-law (Section 17) relating to meetings of Fellows and Members, and the possibility that the Council might apply he phrase "disgraceful conduct" to political actions directed against the government of the College. The Council of the College replied in detail to the letter from the Society of Members to the Home Secretary, with the result that Mr. ASQUITH suggested that the objects which the Council had in view would be obtained by a by-law couched in terms similar to those of Section 29 of the Medical Act of 1858. This solution of the difficulty was at once accepted by the Council, and the incident terminated. As now enacted Section 16 will enable the Council to deal with many cases of misconduct of which, under the limited scope of the former by-law, they were unable to take cognisance, and will remove the disability under which the Council were not infrequently precluded from taking action against Members of the College whose names had been removed by the General Medical Council from the Medical Register for "disgraceful conduct." Section 7 of the Report, relating to the Primary Examination for the Fellowship, is an instructive example of "how not to do it," which might have been copied from the celebrated "Circumlocution Office" of DICKENS. In June, 1892, the examiners in physiology for the Fellowship submitted to the Council a scheme for the practical part of the examination in physiology, but, several changes being made at the June meeting of the Council among these examiners, the scheme was referred back to the altered Board. An amended scheme was submitted to the Council in June, 1893, and this scheme was then referred to the Nomination Committee. In May, 1894, the Nomination Committee and the examiners discussed the scheme together, when it was found that two examiners were in favour of the scheme and two opposed to it. Nevertheless, at the request of the Committee, the examiners drew up a syllabus defining the scope of the proposed examination. The Committee considered the syllabus and visited the Primary Examination for the Fellowship in November, 1894, finally recommending that no change should be made. This battledore-and-shuttlecock method of dealing with the examination in practical physiology, which was kept up for two years and ended in nothing being done, will be found to be the usual mode of procedure in regard to all questions of education or examination which come before the Council. The game is usually triangular, the parties to it being the Council, a special committee of the Council, and the Nomination Committee. Occasionally the medical schools are asked to participate in the exercise. This has been the case recently with regard to the proposed institution of a special examination in ophthalmology, which, according to the Report, is still *sub judice*, and which will probably be dealt with in the Report for 1896 or 1897.

The question of the admission of women to examination at the College, which has arisen out of a memorial to the Council from the London School of Medicine for Women, will be submitted to the annual meeting for discussion before it is formally debated and finally determined by the Council. This question will be submitted in redemption of the Council's undertaking, first made in 1885, to take the opinion of the Fellows and Members in "the larger constitutional questions which more rarely arise." In view of the claims which the Members of the College are putting forward for an increase in their privileges and for representation on the Council of the College, Section 16 of the Report, relating to finance, is a most important one. It comments in detail on the various items of income and expenditure during the past year. The statement itself is taken from the annual report of the Finance Committee; and we are sorry that that report has not been reprinted in its integrity, as the omitted parts related especially to the large decrease in the examination fees and offered some remedial suggestions. So far as it goes, however, it is sufficiently significant and instructive. The expenditure of the College for the year is £376 in excess of the expenditure of the previous year and nearly £750 more than the amount which had been estimated by the Committee, and though there are some heads under which the out-goings for the

Digitized by Google

current year will probably be reduced there are others under which it will be greatly increased, and the Committee estimate that the expenditure will be heavy. Unfortunately the income of the College is not likely to increase. During the past year it was £537 less than in the previous year, and the main decrease is due to the smaller receipts from the examinations, and chiefly from the examinations for the Membership of the College, the receipts from the First and Second Examinations continuing their downward course. The decrease is partly attributable to the addition of a year to the curriculum of study, which innovation has now been in force for two years; but we strongly suspect that the bulk of it is due to a loss of popularity by the College. The Council will probably soon begin to see that the prosperity of the College depends not upon the Fellows but upon the Members of the College, and that if the institution is to continue to flourish measures must be adopted to attract the rank and file of the profession and to counteract the competition of the universities and other bodies. The needs of the College will be the opportunity of the Members, and it rests with the Members themselves to make the most of the opportunity thus presented to them. A temperate exposition of their claims and a firm, but conciliatory, attitude will tend to enlist the sympathies of the Fellows, of whom not a few are, we have reason to believe, convinced that the Members are justly entitled to a share in the government of the College and to representation on the Council. At the annual meeting, if we set aside the women's question, the course will be clear for the Members, and we sincerely trust that those who speak in their behalf will display that unruffled temper and that calmness and cogency of argument which are worthy of the great and important cause which it is their privilege to advocate.

Annotations.

"Ne quid nimis."

THE STUDY OF LEGAL MEDICINE.

THE Medico-Legal Society of America is an institution of established position in the United States which devotes itself to the advancement of legal medicine. The study is one that in recent years has grown very markedly both in importance and in precision; indeed, these two aspects really represent under different points of view one and the same advance. It is precisely because in recent years the scientific bases upon which it rests have gained in breadth and exactitude that the practical aspect and application of the study have gained in importance. But at this point we pass from the precise sphere of legal medicine and enter those of physical science on the one hand and of jurisprudence on the other. New instruments within the last quarter of a century have opened up new fields of investigation and laid bare new ways of approaching truth, but the discovery of the principles upon which these new inventions rest and their adaptation to the physical uses to which they can be applied are tasks that fall within the sphere of the physical sciences rather than within that of medical jurisprudence. The medical jurist takes these things as data and proceeds to ascertain how they can be utilised in the practice of the law and to what extent they necessitate or suggest improvements in the existing methods of procedure. The same thing may be said of the development of mental pathology. Criminal responsibility and the right to be the custodian of one's own affairs, although matters of profound interest, are too special to be studied apart to any advantage. Both depend upon the general relationship between the individual affected and society at large. All that the student of forensic medicine can do is to apply in this department the results reached by workers whose interest is primarily engaged with the morbid facts themselves, and he must thus be content to walk in the wake of *confrères* who are occupied with the more elementary facts. But in recent years the progress all along the line of scientific investigation and discovery has been so rapid that the difficulty with those who labour in the field of the applied sciences has been to keep the pace and not to make it, and so it comes to pass that the Medico-Legal Society, in common with many kindred institutions, is able to show an excellent record of progress achieved in the region which chiefly engages its attention. It must not, however, be supposed that in pointing out the dependence of legal medicine upon the physical sciences we are in any way disparaging the work of those who have the practical end of improved juridical practice directly in view; on the contrary, we desire to point out that their labours clothe the abstract scientific truths with new significance and harness them to serviceable ends. And in this direction there lie great possibilities of usefulness before the American society.

GOOD AND BAD TEETH.

THAT the tendency to decay of the teeth is in some way dependent on a deficiency of lime salts has often been assumed; it is only lately, however, that crucial investigations can be said to have settled the question. In a series of remarkably interesting articles, concluded in the current number of the Journal of the British Dental Association, on the Analysis of the Teeth, Mr. Charles Tomes records some quantitative estimates of his own and compares them with those of Dr. Black recently published in America. After describing in detail his method of estimating the various constituents of dentine, obtained from sets of teeth in his own possession, Mr. Tomes remarks: "Taking all teeth examined the percentage of lime salts in dentine is 71·9. "I am inclined, however, to think Dr. Black is right in thinking that the percentage of lime salts is not the factor which determines the liability to caries, for in one set of teeth, in which the wisdom teeth were barely in place, two bicuspids had been largely affected, there was incipient caries between many of the teeth, one wisdom tooth was badly decayed, and the incisors were markedly striated transversely; yet this set of teeth gave an average of 71·4 per cent. of salts, whilst another much worn dentition, quite free from any trace of caries, also gave 71·4 per cent. of salts; that is to say, both were 0·5 below the general average." It must certainly come as a surprise, not merely that teeth which we recognise as types of vigorous, healthy formation should be no better off in lime salts than those presenting all the signs of liability to decay, but, moreover, that teeth worn down by attrition, in which it has been assumed an extra calcification has taken place, should actually be below the average percentage of lime salts. Another curious outcome of these investigations arose from a statement by Dr. Black that there were differences in the amount of mineral matter in teeth taken from the same individual. Mr. Tomes, in confirmation, adds: "But I also find an unexpected fact which is of much interest. The differences are not fortuitous, for I have found that the incisors and canines uniformly contained a smaller portion of mineral matter than

Digitized by Google

the molars." He gives the proportion as follows: incisors, 71·2 per cent. inorganic salts and 28·8 per cent. organic matter and water; molars, 73 per cent. inorganic salts and 27 per cent. organic matter and water. This further appears to support the view that the proportion of lime salts is not a chief factor in the production of decay, for the molar teeth are certainly more prone to decay than the incisors, although according to these figures the former are richer in lime salts than the latter. Mr. Tomes has promised to carry his investigations further; meanwhile he suggests that "the difference between good and bad teeth may lie in the amount of combined water, in the proportion of calcium carbonate, in the nature of the organic matrix, or, finally, it may not lie in the dentine at all, but may be a difference in the enamel."

"POPULAR REMEDIES."

THAT the general public are taking an increased interest in medical matters is shown in many ways. Current literature is full of the subject, and the medical element in the modern novel has been referred to in these columns on several occasions. The stage, too, often puts before the public studies in which morbid processes both of mind and body occupy a conspicuous position, and the daily press displays an avidity for the latest cures of incurable diseases. This is the burden of Dr. Nestor Tirard's excuse for taking "Popular Remedies" as the subject of an address which he delivered on Monday last before a lay audience at King's College, London. Dr. Tirard laid most stress on the folk-lore aspect of the subject, and from this point of view there is a wealth of interesting material, humorous and instructive, which might well occupy the attention of both the lay and the medical public. Many of the old popular remedies, while absurd in their composition as a whole, contained one ingredient which undoubtedly possessed a therapeutic value, and the other components of the remedy were introduced merely to minister to that innate craving of humanity which is for ever seeking after the rare or mysterious. On the other hand, the principle of faith-healing no doubt underlies the old recipes which contained drugs and things of no known therapeutic value whatever. General attention to diet, exercise, sleep, and the use of hot and cold water internally and externally, and a "return to the ways of physiological righteousness," may do much to cure diseased states of the body. All these things were done or brought about if the patient religiously followed out the instructions in many of the old prescriptions; for, amongst other things, the patient had often to collect the ingredients composing the prescription himself, and this would frequently entail early rising (for some plants had to be gathered early in the morning); and active exercise where the object sought was rare and difficult to obtain. The aspect of the subject, however, which will most interest our own profession is that which the lecturer touched upon when speaking of modern popular remedies as exemplified in the growing fashion for using Murphy's Merciless Mixture, Pongo's Puerile Pills, or Pudge's Pungent Plasters. As when we hear a tune played for the first time on a street organ we perhaps take no notice of it, and later, hearing the same tune again, we recognise it as the tune we previously heard, and hen by-and-bye the catchy air has so insidiously worked its way into our brain that we catch ourselves humming some music-hall song of which we do not know the words, and if we did should not, probably, give utterance to them, so the alliterative titles of the specious patent medicine advertisements play upon the mind of the public until familiarity brings about the desired object of the advertiser. Another cause which the lecturer thinks contributes to the popularity of these nostrums lies in the growth of medical knowledge. The young medical men of the day, believing the cure of certain morbid conditions of the body to be hopeless, instead of attempting to battle with these conditions, tell their patients that nothing can be done for them. And here is the opening for the nostrum dealer, who promises everything and whose statements are always positive and never negative. The popular remedies of a nation also afford some index of its health and habits, and, in spite of the views often expressed in works of modern fiction, the moral health of this country has of late been essentially respectable, for an analysis of the drugs used in prescriptions for the past ten years shows that tonics, stomachics, and such-like drugs are of far more frequent use than preparations of mercury and iodide of potassium.

BATHS AT BATH.

SOME friction has been caused by the management of the baths at Bath. The committee a few weeks ago, at the suggestion of a well-known physician, decided to introduce the "Thermalsoolbad," so that patients could have this method of treatment without the trouble and expense of going to the Continent. The committee passed a by-law as to the use of the bath which was thought to be somewhat stringent, and most of the medical practitioners of Bath felt themselves aggrieved at this. Some of the inhabitants, too, are complaining of the extra expenditure at the baths, but as these form the chief attraction of the city the majority of the residents will not hesitate to keep their baths up to the highest state of perfection. There is only one member of the medical profession on the Baths Committee, which is certainly not sufficient, considering how many medical men in Bath are interested in the baths and have patients using them. If the profession had been more fully represented on the committee the friction alluded to in all probability would never have occurred.

"MORAL PATHOLOGY."

WE are coming to speak of a modern science of ethics as of some new revelation, and such in a sense it is. In the same way we talk of a new planet. Both, in fact, are ages old, but are now for the first time explained to us by a new interpretation. There nee be no surprise, therefore, when we find that many suggestions and assertions made in our own day on the authority of original thought and observation have long ago found expression in other phrases, whether these be the maxims of daily practice, the records of independent reflection, or the accepted doctrine of sacred writings. To explain these truths anew in the language of cause and effect is not, therefore, to teach them for the first time, but to corroborate them by establishing their essential connexion with other facts of life. Ethical science thus becomes a reconciler of opinions respecting the natural and what we have known hitherto as the supernatural. Its teaching goes far to verify the real unity of terms apparently so diverse and to show that the laws of action to which they are related are often, if not always, virtually identical. Recent literature has repeatedly furnished us with suggestions illustrative of this unity. The processes of biology, social usage, and morality have again and again been proved to follow similar lines of action, and this resemblance is, perhaps, nowhere better seen than in the parallel changes observed in physical disease and moral disorder. We have before us an interesting contribution to this subject in a handbook on "Moral Pathology" by Dr. Arthur E. Giles. In a series of brief chapters he traces the progressive effects and variations of moral evil from its probable origin in some act of bodily indulgence—some "fall" of the man, or rather of the child—through further developments to the more or less complete deformation of character. The analogy

Digitized by Google

between moral wrongdoing and disease is carefully and closely followed throughout, and is described with force and clearness. The moral physician, in order to treat successfully the complex forms of soul sickness with which he has to do, must, as is truly said, be equally well endowed with insight, sympathy, experience, and the influence of personal example. A chapter on moral diatheses will instruct very many. The right use of egoism as a motor of good actions is worth noting, so also is a chapter on the causation of moral disease. We have been particularly attracted to the observations on selfishness; in opposition to this vice we seem to find the clue to a perfect reformation. Dr. Giles's preference for healthy altruism as a remedy rather than for merely negative self-sacrifice will commend itself to most readers. It is encouraging to find that even in a study so sombre as moral pathology we are in sight of a hopeful prognosis. Moral death, it is maintained, is unknown to man, though a species of soul coma is not. Recovery is always possible, provided that the will, captive to evil, be aroused to efforts of release by a stimulus of sufficient power. The remarks on treatment, though necessarily short in a work professedly descriptive of disease, are characterised in an eminent degree by friendly wisdom and practical good sense. In particular we may notice three: (1) that careful moral training should begin in childhood; (2) that such instruction should at any age and as far as possible be individual rather than general; and (3) that in order to succeed it must be sympathetic. Such rational suggestions as the above are of happy augury when we regard them as expressing the active purpose of the new and yet primeval science of ethics.

TUBERCULOSIS OF THE BONES, MUSCLES, AND EYES OF CATTLE.

IN the inspection of the carcases of animals destined for the food of mankind something more is necessary for the detection of tuberculosis than a cursory examination of the lungs and lymph glands, as the lesions are sometimes observed in the hard tissues and muscles, which are not usually cut into for investigation. In a German periodical devoted to the hygiene of flesh and milk the remark is made as to the comparative infrequency of tubercles in the flesh of cattle, and especially in the myocardium. In the latter situation only one instance had been observed until recently; this was in a cow which had very extensive tuberculosis of the pleura, and in the wall of the right ventricle there was a tuberculous mass as large as a bean. Not long ago at the Leipzig abattoir a calf six weeks old and in good condition was slaughtered, and on dressing the carcase it was found to be affected with generalised tuberculosis—the lungs, pleura, and lymphatic glands of the neck, chest, and abdomen, as well as the liver, spleen, kidneys, &c., being involved. On the right side of the heart, near the surface, and only separated from each other by a thin muscular partition, were two masses of tubercle, each as large as a hazel-nut. One was embedded in the wall of the left ventricle, near the auriculo-ventricular groove, and the other at the apex of the organ, on the middle of its anterior surface. Another veterinary abattoir inspector had some time ago discovered a case in which there was tuberculosis of the sternum, the elbow-joint, and the pectoral muscles. More recently he has met with another instance of muscular tuberculosis, which was apparently not primary, but consecutive to tuberculosis of the cartilage of the seventh rib. The latter was completely destroyed at certain points, the remaining portions containing yellow, rounded, cup-shaped nodules, which when removed left circular cavities that neither in colour nor appearance could be distinguished from normal cartilage. Around the diseased cartilage there were seven small abscesses, one of which was open; the pus in these contained the tubercle bacillus. The cow was the subject of thoracic and abdominal tuberculosis. There are a number of cases of ocular tuberculosis in the ox recorded in veterinary literature, and among the latest are two described by Herr Winter of Bromberg. The first case was that of a four-year-old Dutch cow, which was so stupid or stupefied as to be insensible to the voice and to blows. At its necropsy generalised tuberculosis was noted, the pleura, lungs, peritoneum, lymphatic glands, liver, kidneys, ovaries, and udder, as well as the brain and its coverings, being diseased. The cornea of the right eye was opaque, bluish-grey in some places and bluish-black in others. Near the internal angle there was a prominent mass formed of lenticular tubercles, and the sclerotic also showed pyriform and lenticular projections that appeared to come from the interior of the eye. At the junction of the cornea with the sclerotic there was another mass of the diameter of a 50-centime piece. The interior of the ocular globe was fully occupied by a caseous mass, bright yellow in colour, semi-fluid, and containing calcareous particles. At the papilla of the optic nerve the retina was separated from its deeper layer by cheesy tubercles; the prominences seen on the outside of the sclerotic were found to be situated between that and the choroid coat, and were calcified in some places and puriform in others. The crystalline lens could not be recognised, and the iris was confounded with the cornea. By the aid of the microscope tubercle bacilli were found everywhere. The other case was that of an emaciated cow also affected with generalised tuberculosis. The right cornea was turbid and of a dark-blue tint; at the margin of the sclerotic there were several yellowish tubercles each about the size of a lentil; the vitreous humour was muddy and opaque, but the retina and crystalline lens were normal. The posterior surface of the iris was partially adherent to the lens by a thin white layer, and on its anterior surface there were nodules which could be seen through the cornea, with yellow miliary tubercles grouped in tufts or in grape-like masses at its lower border where it joined the cornea. In all these neo-formations the tubercle bacilli abounded.

WHEN IS SKIMMED MILK NOT SKIMMED MILK?

MR. HADEN CORSER, the magistrate at Clerkenwell Police-court, expressed himself in the following terms last week on the occasion of a summons against certain refreshment-room proprietors for selling to their customers milk from which the fat had been abstracted to the extent of 15 per cent.: "I am sorry my judgment is bound by the case which has been decided in a superior court. I consider the section referred to was passed to prevent wholesale milk-sellers or retail dealers from skimming off the cream and knowingly selling poor milk. I am bound by the decision of the higher court, although I am convinced an injustice has been done. I am bound to do an injustice in this case because a superior court orders me to do it. I shall impose a fine of 6*d*. and the cost of the summons." Mr. Haden Corser urged, as the basis of these remarks, that if milk were put in a pan the cream rose to the top and the early purchasers got it, whereas if it were sold from an urn with a tap those who came last received all the cream. But what if the milk had been skimmed before it was put in either of these receptacles? We want to make no imputation, but we cannot gather a particle of evidence that such was not the case; at any rate, such a case could easily occur. What an excellent loophole of escape, then, would Mr. Haden Corser's judgment afford. The milkman or vendor would only have to say that his milk was put in a pan and the cream rose to the top, and the early birds—no, the early purchasers—got the cream, or that the milk was sold from an urn with a tap, and those who came last received all the cream. In Mr. Haden Corser's

Digitized by Google

judgment this is good defence, so that the only question to be decided is, What kind of vessel was it from which the milk was poured? The cream, however, or the bulk of it, may never have been put in, be it pan or urn. We are not sorry, as Mr. Haden Corser was, that in this case his judgment was bound by a similar case which had been decided in a superior court. The occasional use of a stirrer would have obviated the necessity of bringing the case before Mr. Haden Corser at all, granting, of course, that the cream had been there.

THE EDIBLES AT COUNTRY FAIRS.

A DEATH and illnesses which occurred recently at East Liss, on the eastern borders of Hampshire, seem to point to the need of a more stringent inspection by sanitary officers of the edibles sold by itinerant stall-keepers at country fairs and feasts. A labourer bought some fried fish at a stall at Petersfield fair which made him very sick. He went to work as usual next day, but was very ill, and returned to his lodgings, having lost the use of his limbs. A medical man who was called in found every symptom of poisoning, and the necropsy confirmed the opinion that the death was due to the diseased fish which the man had eaten. Several instances of slight illness included the experience of another labourer, who ate very little of the fish he bought, as it "tasted so unwholesome." The police were unable to trace the vendors in this case, but a prior inspection of the barrows might have obviated a fatal result. It is, perhaps, a matter of wonder that we hear of so few fatal illnesses contracted from the consumption of the contents of the evil-smelling and dirty conveyances of peripatetic costermongers.

THE ISLINGTON INFIRMARY.

WINTRY weather has set in this year somewhat earlier than its wont, and with it has come the usual influx of patients into the metropolitan Poor-law infirmaries. A few days' frost or fog seriously interferes with the out-door employments on which so many of the unskilled London workers depend, pulmonary and rheumatic troubles show themselves, no money can be earned, and the relieving officer is the only resource. The poor also know that in time of sickness they will have in the infirmary good accommodation, food, nursing, and medical attendance, a combination of benefits unattainable in their own homes; and the natural consequence is that these applicants for what is primarily medical relief are sometimes so numerous as to cause anxiety to the parochial authorities. There is every prospect that the Islington board of guardians will have a difficult problem to solve during the next two or three months. The parish contains more than 300,000 inhabitants, and as early as the middle of October the inmates of the workhouse and infirmary largely exceeded the regulation limit. According to the official certificate the workhouse can accommodate 781 persons and the infirmary 473; but, as a matter of fact, there were 595 patients in the infirmary on Oct. 13th. Now these are not, as a rule, chronic infirm patients, lingering out their last years and in but slight need of medical attendance; on the contrary, this infirmary is a busy hospital, into which during the present year 1365 patients were admitted from Jan. 1st to May 7th, and 236 deaths occurred during the same period. This gives a weekly average of nearly 76 new admissions and 13 deaths, and some of our readers will hear with surprise that the labour and responsibility of bestowing due attendance and care on this aggregation of suffering humanity are shared between only two medical officers. A little computation will show that these gentlemen can hardly give more than a brief consideration to individual cases, and as far back as last July steps were taken by the guardians to create a third medical appointment, but when the day for selecting a candidate arrived the guardians changed their minds and decided that an additional medical officer was unnecessary. The question of providing further accommodation for the sick and destitute cannot be solved in this easy manner. Apparently the guardians hope to surmount the present difficulty by resorting to extemporised structures, but there is no reason to suppose that the winter admissions of sick and destitute persons will be less in the future than at present, and the wisest policy would no doubt be the prompt construction of a new infirmary on a site sufficiently spacious to permit the erection of such additional buildings as may from time to time be required.

BRAVERY.

"HEROISM without risk" was the motto of Mr. Gilbert's band of brigands, but the heroism that is attended with risk is widely exemplified in this (Thursday) morning's papers. The death of Fireman Sprague is a sad comment on the dangers encountered in coping with a fire, and the valour displayed by him and his companions is by this time known throughout the land. Women, too, are not laggards in bravery. The *Times* reports that the Royal Humane Society have just presented three ladies—Miss K. Gelling, aged sixteen, Miss Violet Ponsonby, aged eighteen, and Mrs. G. Anderson—with testimonials for saving life. The last-named nearly lost her life in saving a boy who was bathing at Sherringham; Miss Gelling saved a boy bathing at Castletown; and Miss Ponsonby swam out, fully clothed, into the Cookham rapid and saved a lady who was upset from a canoe. These ladies are to be congratulated on their pluck and the success which attended their efforts.

THE FACIAL NERVE AND LACRYMAL SECRETION.

IN a recent number of the *Deutsche Medicinische Wochenschrift* Dr. Franke of Greifswald makes some remarks with reference to the anatomical, physiological, and experimental evidence regarding the nerve controlling lacrymal secretion. Krause's conclusion that the trigeminus has a decided influence on this secretion and that the facial also takes some part in its control is alluded to. The evidence for this lay in the fact observed by Krause that complete extirpation of the Gasserian ganglion did not cause a complete cessation of tears in the eye on the side on which removal had taken place. Dr. Franke is inclined to refer this effect, however, to injury to the greater superficial petrosal nerve. The patient whose case Dr. Franke describes showed complete paralysis of the left side of the face with only slight secretion of tears on the affected side, although the trigeminus was intact. His view is that the facial nerve is the nerve of the lacrymal gland, and that disappearance of the secretion is determined by a lesion of the facial nerve either involving the geniculate ganglion or an even more central part.

THE DELMAR CHARITABLE TRUST.

MR. F. O. T. DELMAR of Bayswater, who died on Oct. 14th, has left £100,000 to his trustees to form a fund to be called the Delmar Charitable Trust. Nine-tenths of the annual income from this fund is to be divided between selected charitable institutions in London or its neighbourhood, "having regard to the relative importance and magnitude of each institution." The testator expresses his desire to benefit in particular the establishments for the care and treatment of epileptic and cancerous patients and the Royal Society for the Prevention of Cruelty to Animals. It is to be hoped that the trustees in their wisdom will select for the benefit of this bountiful bequest those institutions more especially which

Digitized by Google

have been established long enough to have a record of ably administered benevolence, as this is the surest guarantee that the charity has gained the confidence of the public. The Cancer Foundation of the Middlesex Hospital stands almost alone in this respect, and certainly deserves a substantial share of such support as the trustees can legitimately divert to it. Founded in 1792, this permanent refuge for victims from cancer still shelters the sufferers until "relieved by art or released by death," and the present is a peculiarly appropriate time for rendering it pecuniary assistance. His Royal Highness the Prince of Wales presided last year at a festival dinner to raise funds for providing a separate building for patients suffering from incurable cancer, and up to the present time a sum of over £8000 has been subscribed. But the building will cost at least an additional £4000, and further donations to the endowment fund are earnestly invited by the governors of the charity in order to maintain these poor afflicted people in comfort and thus relieve a severe strain upon the general funds of the hospital.

THE WATER-SUPPLY OF HIGH BUILDINGS.

THE immense height of the colossal office and business buildings in the lower part of New York, where there are scores of buildings ranging from twelve to twenty storeys high, is, says the current issue of the *Leisure Hour*, bringing forward a serious problem in connexion with water-supply. New York has an excellent water service from its great reservoirs at Croton, where its waterworks compare with those of any of our own large cities. The water service gave satisfaction until the era of twenty-storey buildings began. Since then owners and tenants of these tower-like structures have been complaining that they are never able to obtain water on the upper floors. The difficulty principally affects buildings of more than fifteen storeys. The owners of the buildings recently formed themselves into an organisation and deputed a committee to discuss the position of affairs with the mayor. It was then made plain that the fault was not entirely with the supply of water. That was sufficient to meet the needs of these tall buildings. The water could be forced into the topmost storeys of them; but to do so would demand a pressure which would wreck the water fittings in at least seven-tenths of the other buildings and dwelling-houses in the city.

THE DANGERS OF DUELLING.

ALTHOUGH in the great majority of cases duelling with the sword is not nowadays a very serious affair, the wounds inflicted being generally of a trifling nature and by no means dangerous to life, still occasionally, and especially when one or other of the combatants is a tyro with his weapon, graver consequences may ensue, and the contest which for the most part is regarded as a formality becomes converted into a fatality. When the pistol is the weapon employed for the adjustment of disputes, it would at first sight appear as though the risk of the encounter was considerably augmented; but experience has proved that the firearm is a far less lethal instrument of offence than what our Gallic neighbours call *l'arme blanche*. This, no doubt, is owing to the fact that ninety-nine men out of a hundred are excessively bad shots for want of practice, being unable, as the saying is, to "hit a haystack flying." In the early years of the present dying century pistol shooting was an essential portion of every "young blood's" education, and none were considered proficient until they could hit the ace of hearts at sixteen paces, but happily the barbarous practice has now completely died out even on the Continent, where duels are not yet quite defunct. The foregoing reflections have been suggested by a sad occurrence which recently took place in Corsica. In consequence of a newspaper article Dr. Alessandri, a retired naval officer, challenged the editor, whose name is Benedetti, and a duel with pistols was the result. Shots having been exchanged at thirty paces without effect, the weapons were reloaded, and the combatants once more confronted each other. The signal was given, two shots sounded as one, and the unfortunate Dr. Alessandri fell to the ground with a mortal wound in his right side, from which he shortly afterwards expired. Death was almost instantaneous, being due, as was shown subsequently at a post-mortem examination, to a severed pulmonary artery. The deceased, who was a Chevalier of the Legion of Honour, had seen a considerable amount of service. As the President of the General Council, who pronounced the funeral oration, said: "It was heart-rending that a distinguished surgeon, who had passed without a scratch through several campaigns, should fall a victim to hazard in a paltry encounter which owed its origin to the rancour of political passion."

THE INTERCOMMUNICATION OF HUMAN AND ANIMAL DISEASES.

IN our correspondence columns is published a letter from Dr. J. W. Allan suggesting the formation of institutions where the intercommunicable diseases of man and animals could be practically investigated. There can be no doubt as to the importance of such investigation so far as mankind is concerned, for the human species incurs much more risk of danger from the existence of communicable disorders in animals than do animals from such affections in human beings. However desirable it may be to have such investigations thoroughly carried out, there are grave obstacles to be encountered in founding such establishments, the first and most important being the provision of money. It is almost certain that the Government will not provide it, and it is to be feared that private benevolence cannot be relied upon to achieve this object. So that it is to be apprehended we must rely upon the establishments we already possess for the investigation of allied subjects, such as the histological and pathological laboratories of the medical and veterinary schools, and special foundations like that of the British Institute of Preventive Medicine, to afford opportunities for learning more of these transmissible diseases. There are now many labourers in this field, both in this country and abroad, and it must not be forgotten that the Local Government Board has for many years past spent considerable sums of money in the investigation of those disorders of animals which can be conveyed to man. With regard to the suppression of these diseases it has also to be remembered that medical opinion is, at least, as regards some of them—rabies and glanders, for instance—ahead of public and legislative opinion.

AMERICAN VIEWS OF ANTISEPSIS IN MIDWIFERY.

THE *New York Medical Record* of Oct. 5th gives an interesting report of a discussion on the importance of asepsis in the practice of obstetrics at the Medical Society of the County of New York, in which a comparison is made between the methods and results of aseptic and antiseptic midwifery as practised in four city institutions and the same in the private practice of four physicians. In the institutions the mortality was about one-eighth of 1 per cent., while in the practice of the physicians it was one-fifth of 1 per cent. The chief difference in the methods was that in the hospitals the vaginal douche was practised before and after labour and the pubes were shaved. The latter seems to us a very questionable procedure, and the vaginal douches are only less so. As to the great points of aseptic towels, cleaning the genitals, washing in the antiseptic sense the accoucheur's hands, there was a general consensus of opinion.

Digitized by Google

and it is obvious that any practitioner who neglects thoroughly to wash his hands and nails and to preserve the asepticism of his clothes is not doing his duty to his patient. The private practitioner must not allow his success to fall below that of the public institutions. Dr. Reid, the writer of the paper, while not objecting to the details of hospital asepsis, did not think all of them necessary. Dr. Tucker was glad to hear a private practitioner express the opinion that milk fever was septic. He himself thought it usually so, not always. Dr. R. A. Murray emphasised the importance of personal cleanliness in the physician. "When the physician kept himself and his hands clean he did not have sepsis, no matter what the surroundings of the patient." Dr. Reid had had but one death from sepsis in his last 458 cases. Dr. Thomas Darlington as a private practitioner made not the least interesting contribution to the discussion. In country or sparsely peopled districts he frequently found none of the amenities of antisepsis. Soap, boiled water, or water of any kind (!), were conspicuous by their absence. His success was the record of the debate. "He had confined nearly 1000 women and had lost none from any cause. Whenever there was sepsis he believed it came from the physician. He carried bichloride tablets to wash his hands. He thought the vaginal secretions helped the passage of the head and that the douche retarded it." There is a ring of common sense about these last remarks which will impress them on private practitioners and fasten on them the responsibility of clean aseptic hands.

A CHILD'S RIGHT OF ASYLUM.

IT is to be hoped that we have not yet heard the latest explanation of a case of cruelty recently decided in the Marlborough-street Police-court. A child, after being grievously maltreated by her mother, had been removed to the shelter of the Society for the Prevention of Cruelty to Children. The mother, fearing prosecution, endeavoured to resume possession of the child, but was prevented on the request of the latter by the society's officials. It will be remembered that special provision is made by the Acts relating to this form of cruelty for such an appeal as this, and also that officials in charge of the society's shelters are entitled to give it effect. Naturally, therefore, many persons have been surprised by the announcement that a stipendiary magistrate of recognised ability has taken an exactly opposite view of the merits of this case, has denied the legality of the society's action, and has insisted on restoring the child to her mother's keeping. We confess that after a careful examination of the facts upon which it is founded the justice of this decision entirely baffles our comprehension. It would be interesting to learn what form of sanction can be pleaded in its support. So far none is evident, but, on the contrary, the process of justice and the practical utility of the Acts appear to be hopelessly irreconcilable. If, as would seem to be the case, the right of appeal conferred upon children subjected to ill usage cannot be exercised without a near prospect of parental retribution, it is obviously a right of merely nominal value.

SHAMS.

MR. WILLIAM BENJAMIN DAVIES has recently been fined £22 4*s*. for infringing the Medical Act by falsely taking and using the title of a surgeon. According to his solicitor, Mr. Davies had gone through the usual medical training up to the final examination, from which he withdrew, so it is quite possible that his medical knowledge was fairly good. But he represented himself as being what he was not, and richly deserved his punishment. His offence is only too common nowadays in every department of trade. You ask for bread and butter and get presumably bread—though no one has yet defined what bread is—and certainly margarine. It is fair to state that in a recent case the purchaser was told beforehand by the vendor that he would get margarine. Ground coffee is openly sold as a mixture of chicory and coffee. It is useless to say most people like it so—ninety-nine out of a hundred English people do not know what coffee is. In an evening contemporary was recently printed a prize menu for two people to last a week; among other items was a quarter of a pound of coffee, price 4*d*. Conceive the infusion made from four ounces of coffee at 1*s*. 4*d*. a pound to last two people a week; but this kind of wash is the average housewife's notion of coffee. A return to the methods of our ancestors—the quack paraded through Cheapside with a collar of "jordans" round his neck, the adulterator, whether wholesale or retail, in the pillory at Charing-cross, with his falsely named goods at his feet—would go a long way towards purifying money-getting and preventing robbery. An even more stringent punishment than these is on record, the case being that of a falsifier of wine, who, being compelled to drink some of his product, died. Perhaps if this was carried out in every case the effects would be too uniformly fatal, but the suggestion is one to be borne in mind.

CEREBRAL TUMOUR AND HYDROCEPHALUS.

DR. DINKLER recently published in the *Deutsche Zeitschrift für Nervenheilkunde* a case of more than usual interest, both in its clinical course and in the nature and extent of the morbid conditions which were present. The following are the particulars. A child, without any hereditary morbid tendency so far as could be discovered, was seized in his third year with a vague illness, from which he speedily recovered. About four months before his admission, being then of the age of four, he was found to have distinct weakness of the upper part of the body and head, the weakness being revealed in sitting, standing, or walking. He also apparently lost control over bladder and rectum. He was found to have a fairly big head, sluggish pupil reactions, swollen discs on each side, weakness of the right side affecting the face and limbs, normal sensibility, and an increased knee-jerk on the right side. After a few days there were sickness, somnolence, and finally loss of consciousness; after four weeks an epileptiform attack occurred, with twitchings of the left side of the body, and there were increased reflexes on both sides, and after three months paresis of the left leg and an increase in the circumference of the head. On each side there was distinct optic neuritis. On account of the increasing size of the head puncture of the dura mater was performed between the third and fourth lumbar vertebræ, and a large quantity of fluid was withdrawn. The pulse, however, again became slow and finally irregular, and death occurred seven months after the patient came under observation. The diagnosis which was arrived at was one of cerebellar tumour with hydrocephalus, but at the necropsy it was found that there was a huge tumour of the *right* cerebral hemisphere besides severe internal hydrocephalus. Microscopical examination revealed a high degree of degeneration of the *left* cerebral cortex and atrophy, through pressure, of the right parietal lobe. There was no degeneration in the cerebellum, pons, or peduncles, but in the spinal cord the posterior columns and roots, from the cauda equina to the first cervical nerve, were very much degenerated. The following is Dr. Dinkler's view of the connexion of the lesions and clinical phenomena. The illness at three years of age had as a sequel internal hydrocephalus. Then, in consequence of the advent of a tumour in the neighbourhood of the right supra-marginal gyrus, the symptoms of intracranial pressure were developed—choked disc, headache, and vomiting. The tumour compressed the hydrocephalus on the right side, causing an

Digitized by Google

enlargement of the ventricle on the left, which led to atrophy and degeneration of the cortex on this side. In consequence of this right-sided weakness resulted, while an extension of the tumour on the right side over the Rolandic area gave rise to weakness as well on the left side, so that before the end there was a condition of double hemiplegia. The main points in the case are the presence of the usual symptoms of cerebellar tumour and the absence of any affection of the cerebellum, and the degeneration of the posterior roots and columns associated with a central lesion. The explanation of this latter condition is by no means obvious.

THE CASE OF MISS LANCHESTER.

ON Friday, Oct. 25th, a Miss Lanchester, whose "views" on the subject of marriage are now public property, was forcibly removed upon an urgency order to an asylum. On Tuesday, the 29th, she was released by order of the Lunacy Commissioners. In the interests of the medical man or men who signed the certificate, no less than as regards the question of the liberty of the subject, an inquiry into all the circumstances is imperatively demanded, and we hope that the proper authorities will promptly initiate such an inquiry.

A DISASTROUS GAS EXPLOSION.

THE past twelve months have been remarkable in bringing into ugly prominence the defects that may happen, and that may be productive of very serious results, in connexion with all three of our service supplies—gas, water, and electricity. It was about this time last year that we were confronted with the dangers of explosion in the street boxes of the electric mains, later (in February) the water mains were frozen, and when the thaw set in the pipes were fractured and several districts were without a regular service for many weeks. To complete an unfortunate trio of disasters a defective gas pipe has now been the means, it would appear, of a sad and most serious occurrence. It happened on Tuesday evening last, in a busy court in the Strand leading to the closely populated district of Clare-market and directly opposite Somerset House. An escape of gas had been noticed in the court for some time, certain repairs had been executed by the gas company not long ago, and on the very day of the explosion men had been employed to make good the pathway. In one or other of these operations it is possible that a defective repair was made, or that a good repair was damaged and converted into a serious leak again by the filling in of the gap and by pressure being probably brought to bear upon the stones or similar materials in making up the hole. With the earthy stuff saturated with gas as it must have been from the previous leak, the fact of a strong smell of gas would not give rise to any suspicion of a fresh leak. It is not difficult to imagine as a consequence that the escaping gas then gained access into and accumulated in the cellar of a house immediately opposite, where it only required a light to produce a terrible explosion. So terrible was the force of the explosion that ensued that a house of three or four floors collapsed completely. During the work of a most plucky rescue amongst the scattered débris an adjoining house fell literally to pieces, burying two firemen, one of whom escaped with slight injuries, while the other remained unextricated for ten hours. He was eventually rescued and taken to King's College Hospital, but the poor fellow succumbed to his injuries. In all, some thirty-one persons were injured, but no other loss of life was reported. We understand that Colonel Majendie has inspected the scene of the disaster with a view to ascertaining its precise cause. Though there seems little doubt that the disaster was due to a considerable escape of gas, it is stated by an evening contemporary that there appears to be a suspicion that some miscreant had been connected with the occurrence, for the authorities of Scotland Yard have been very active in obtaining full particulars. We sincerely hope that any suspicion of this sort will prove to be entirely unfounded.

THE LATE MARK MORRIS.

ALL St. Bartholomew's Hospital men will hear with unfeigned regret of the death of Mark Morris, the steward to that hospital. He was, and had been for many years, so widely identified with the working of the institution that his loss will be, perhaps, more generally felt than that of any other official would be. Everyone liked him, everyone knew him, and there was no one but had the highest esteem for him. If a patient went out of the hospital friendless and in need Mark Morris was ever ready to help him, not only with money or perhaps clothes, but also by genuine sympathy. If an overworked house physician or house surgeon was in despair owing to there being no vacant bed for an urgent case the invaluable steward was applied to and somehow or other managed to provide a bed. His was a striking personality. He somewhat resembled in manner and gait the late Provost of Eton, Dr. Goodford, as portrayed in *Vanity Fair*, and had the same shrewd kindliness of disposition. He was a perfect mine of information as to the history of the hospital, and although an admirable organiser and man of business he was also a fair art critic and an acute judge of old prints, of which he had a good collection. After forty-five years of faithful service he has gone to his rest, and though he will never be forgotten we hope that the governors of the hospital will see their way to establish some tangible memorial of so faithful a servant and so good a friend.

WE have received from the treasurer of Guy's Hospital a copy of a letter from Mr. Gladstone to him urging the claims of the hospital to public support. This eloquent letter has, we are certain, fallen under the notice of most of our readers in the daily press, so that we need not quote its words. If anyone can advance the cause in which it has been written he will be serving the sick and poor in the most efficacious and direct manner.

AS we have intimated, there has been unavoidable delay in the structural alterations of the premises of the General Medical Council, which makes it impossible for the usual November meeting to take place there. It is contemplated to postpone the meeting for some weeks. This is no doubt a serious course; but there are said to be difficulties in the way of holding the meeting in any other place.

THE Lord Bishop of London is, we regret to hear, suffering from a sharp attack of acute tonsillitis. The report, however, as we go to press is that his lordship's condition is much improved, though he is still very weak.

DR. J. B. BRADBURY will deliver the Bradshaw Lecture of the Royal College of Physicians of London, "On some New Vaso-dilators," on Tuesday, Nov. 12th, at 5 P.M.

THE dinner of the Metropolitan Police Surgeons' Association, arranged for Oct. 31st, has been unavoidably postponed.

WE regret to learn of the death of Inspector-General Sir William Mackenzie, K.C.B., C.S.I., M.D., which took place on Tuesday last at the ripe age of eighty-four. Sir William Mackenzie was an honorary physician to the Queen and had seen much service in India under Sir Hugh Rose and Lord Napier of Magdala.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

DEBATE ON THE PETITION FOR ADMISSION OF WOMEN TO THE EXAMINATIONS AND DIPLOMAS.

AN extraordinary Comitia of the Royal College of Physicians of London was held on Thursday, the 24th ult., the President, Sir J. RUSSELL REYNOLDS, Bart., being in the chair.

Communications were read from the Royal College of Surgeons of England reporting the proceedings of the Council on July 29th and Oct. 10th, and asking for the appointment of delegates to confer with delegates of the Royal College of Surgeons of England upon the question of altering the arrangements of the Five Years' Scheme adopted by both Colleges in January, 1892. The delegates of the Royal College of Surgeons of England were Mr. T. Bryant, Sir W. MacCormac, Mr. H. G. Howse, Mr. C. Heath, Mr. R. Harrison, and Mr. T. P. Pick.

The PRESIDENT nominated as the delegates of the Royal College of Physicians of London Dr. Ord, Dr. Norman Moore, Dr. E. Liveing, Dr. Cayley, Dr. Poore, and Dr. F. Taylor.

A petition from the officers and teachers of the London School of Medicine for Women, and of the staff of the Royal Free Hospital and others, praying the College to admit the students of that school to the examinations and diplomas of the College, was read by the Registrar.

Dr. C. WEST, as the senior Fellow present, rose to move that the petition be not granted. He remarked that eighteen years ago the same question was debated in the College, and the admission of women was rejected by 68 votes to 16. The same privilege was sought for now—namely, the admission of women to become members of the College, to take part in its work, and to have the right even of occupying the presidential chair. It was the bounden duty of the College, before granting such a request, to ask the reasons for its being claimed. Quoting from an inaugural address by the founder of the movement for the admission of women to the medical profession, he said that the grounds put forward were those of opening to them a career of serious occupation—one which rendered them independent of marriage for a position, and which saved them from the fear of poverty; and he contrasted such aims with the high and impersonal motives that used to be put before the newly-admitted graduates of the University of Berlin as guiding their career in medicine. He admitted that many fell below these high requirements, but considered that women had duties to fulfil nearer to them than that of following the medical profession; or if they had no home ties there were many other avenues open to them in which to earn a livelihood, such as teaching and nursing, pursuits for which they were far better fitted. But in regard to their claims to follow callings similar to those adopted by men, they were pleading as if they were deprived of their heritage, unmindful of the fact that in all times the highest homage had been rendered to woman. The question of the fitness of women to practise medicine was not in any respect one of their ability to pass examinations. There had always been learned women who were not out of proportion to the number of learned men. But what claim had they to be introduced into the College? What had they done for midwifery, which for a century and a half was entirely in their hands? Even their writers on this subject—as Madame La Chapelle and Madame Boivin—were largely assisted in their works by medical men. They had invented no new procedures, and he would ask what contributions to medicine had proceeded from the female practitioners in America during the fifty years or so of their work there, or from those in England? Had they done anything to raise the standard of medical ethics, and how would medical questions be assisted in debate or otherwise by their partaking in them? Even on the lower ground of expediency there was no need for this change, which was regarded but as a step to their admission to other professions. It was not a mere social change, but a social revolution that was threatened—a "shooting of Niagara." He trusted that all the Fellows would see that it was something more than the dignity of the College that was at stake, it was the whole question of the position of women in the social body, and he expressed the hope that in the interests of women themselves the Fellows would show that they still retained the old spirit of chivalry in spite of the onslaughts made on it by the new woman, and refuse to countenance a movement which might ultimately lead to the revival of the legend of Pope Joan in the occupancy of the presidential chair. He moved: "That the Royal College of Physicians having maturely considered the petition of the officers and teachers of the London School of Medicine for Women, and of the staff of the Royal Free Hospital and others, praying the College to admit the students of that School to the examinations and diplomas of the College, decline to grant the prayer of the petition."

Sir J. FAYRER, in seconding the motion, said that the question was one in which he had never desired to take part, but upon which he felt strongly. He would not follow Dr. West in his arguments of the fitness of women to practise medicine, that not being the question before them, which was one concerning the dignity of the College and the expediency of admitting women to its examinations and diplomas. He did not question their fitness, but he did doubt the propriety of altering the constitution of the College — an ancient corporation of scientific men — for the sake of a dangerous experiment. Such a proposal might indeed be reconsidered after ladies had been admitted to the Senate, Bench, or Bar. Turning to the question of zenana work in India, Sir J. Fayrer said that so far as his experience went there was no difficulty in the way of medical men entering the most jealously guarded harem when there was need for their services, and he thought too much had been made of this argument. There was, indeed, scope for educated women to instruct native women in the principles of prevention of disease, but no need of them as doctors. He said that the many portals whereby women could enter the medical profession proved that there was no necessity for the College to also open its doors, and he failed to see either the expediency or propriety of there being ladies admitted to their meetings; for of course if they were admitted as Licentiates they would qualify to become Members and Fellows.

Sir B. W. RICHARDSON said that he had no desire to encourage women to enter the profession of medicine, but he could not support the proposal to reject this petition to the College. He reminded the Fellows that in the past the College had more than once done injury to itself by refusing to take steps in advance. About ninety years ago it declined to take the lead in establishing a new order of practitioners, so that it was left to the Society of Apothecaries to fill the breach, and for fifty years by itself perform a duty which the College eventually had to take up. So now it was not to the interest of the College that the duty of licensing women for medical practice should be left in the hands of other bodies. He reminded the Fellows that when the College was first founded there had never been a woman at the head of the State, but since then four women had sat on the throne, and it was not consistent to exclude women from medical practice whilst recognising their fitness to govern the country. As to the plea that, were this petition granted, a woman might one day become President of the College, he pointed out that since he became a Fellow thirty-five years ago there had only been five or six Presidents, and therefore it was very improbable that the contingency alluded to would be likely to occur within a period of years, when perchance public opinion may have quite changed, and when possibly women may have failed to maintain their position; and if so, what injury would be done to the College? But if, on the other hand, they rose and became a power, there might not be anything very incongruous in their obtaining the highest offices.

Dr. C. J. HARE felt that it would be a dereliction of duty if he did not express some of his thoughts on the subject. It was true that women could pass examinations as creditably as men; but they had no capacity for creating knowledge or advancing it. They had done nothing in music, although far more of them had studied than had men, who alone filled the ranks of composers. In mathematics there had, it is true, been a Miss Herschell and a Mrs. Somerville, but even these talented women had not extended our knowledge of mathematics. Yet it was asked to admit women into the medical profession, where they were not wanted, and even in India they were not really needed. He reminded

Digitized by Google

Sir B. Richardson that queens governed through their Ministers. The Royal College of Physicians of London was more than an examining body; it represented ethics and was in direct communication with the Government, and he thought its position would be weakened were this change in its constitution to be brought about. Nor did he agree with the opinion that because women were admitted to the profession they must inevitably be admitted into the College. There are many other careers open to them, easier to gain and easier to follow, and until they were made judges or sat on the bench of bishops the question of their admission to the College might be left aside. Until that time came he trusted the College would not change its constitution—established for 300 years—to meet a transient fancy.

Sir W. BROADBENT (Senior Censor) said that he did not hold office when he signed the petition now under discussion. He did not intend to say much, for he supposed that every Fellow had made up his mind on the subject, which no one would consider lightly. Nor would he follow the eloquent address of Dr. West, although he saw no reason why the lofty ideas of professional responsibility claimed for men should not be equally credited to women. Most of the remarks made, so far, had been addressed to the question of the admission of women to the medical profession, but that question *is* decided, and from the first he had watched the experiment with great interest; nor, in his opinion, had it been a failure. There are to be women doctors, and, that being so, they should have the opportunity of coming under the jurisdiction of the College; it would be better for them and the public that they should be under this jurisdiction. Although Sir J. Fayrer said that in his own experience he had no difficulty in attending native women in India, it could not be said that these women received anything like ordinary medical care. It was an injustice to these women who were devoting their lives to this zenana work to deny them the recognition of the College. They desired a higher status, and it was distinctly discouraging to them not to be able to take the College diploma. He recognised none of the evils alleged to follow the admission of women to the medical profession, and said it was not very respectful to the intelligence of the College to advance as a reason for denying their petition that a woman might one day come to be President of the College.

Dr. BARNES had come to the conclusion that the medical education of women must be imperfect, it could not fairly embrace all the diseases of men, and an imperfectly trained practitioner should not be licensed. He emphatically asserted as the outcome of long observation and experience that the admission of women was a degradation of the profession of medicine.

Dr. DOUGLAS POWELL, referring to a document which had been circulated, and had been signed by very distinguished Fellows, said that it contained some very cogent reasons against the proposal to admit women to the College. The question was one which had to be considered: (1) as it affects the Licentiates of the College; (2) as it affects the community at large; and (3) as it affects the constitution of the College itself. On the first point he remarked that there was nothing for women to do in the medical profession which could not be done as well or better by men; and if the over-stocked profession were to be diluted by the addition of women it could not fail to cheapen and degrade (he did not mean in a bad sense) the lower ranks of the profession. As regards the community the College was regarded by the State as the referee in all great questions of public health and the like, and its opinion on the question of the practice of medicine by women was of importance. For if they could enter this profession they were just as fitted to enter any other. This question had not been hitherto brought before an exclusively medical body. In the University of London it was decided against the opinion of the majority of medical graduates by the votes of graduates of other faculties. But now it came before a purely medical authority, which would assume grave responsibility if it lightly dealt with it. For it was a public question. The appropriate duties of womanhood in the home, and in the rearing and training of children, were incompatible with the practice of any profession, which would exhaust her physical and mental energies and divert them from their rightful objects.

Dr. PAYNE, recalling the discussion in the College eighteen years ago, and the eloquent speech then made by Dr. C. West, fancied that some of the arguments used this day had been uttered then, although the state of affairs had much changed. One thing had not changed, and could not be changed—that was the increasing effort of women to earn a living, a fact not due to caprice, but to economical laws. The simple fact is that there is such a large preponderance of women in this country—about a million in excess of men. The women of the lower classes had to earn their whole living, and the same stress was spreading upwards, so that more and more women had to labour. The old avenues were blocked. They could not all be nurses or governesses, and the economical law was forcing them to seek new careers. They did not have to consider whether medicine was a suitable career for women, or whether it was desirable to prevent them or discourage them. Arguments for their total suppression were slightly out of date, and the right principle was that they should be given a fair field. As to women failing to advance science, it is not asked of candidates for the licence whether they are prepared to add to scientific knowledge, but only if they have a competent ability for a certain task. The history of the College had, as Sir B. W. Richardson pointed out, been sometimes marked by a tendency to declare, *Non possumus*. This happened not very long ago when the College refused to coöperate with the Society of Apothecaries in examinations, with the result that the Society remained as a separate diploma-granting body. At one time only graduates of Oxford or Cambridge were admitted to the Fellowship. The Fellows should consider whether it was wise to adopt a purely negative policy on the question before them. Since it was last discussed the experiment of medical education of women had been tried. He had himself examined a large number of women candidates at the University of London, and could say they were of high average. Nor was there any practical difficulty in conducting the examination. He asked whether it was wiser of the College to raise a protest against the movement and refuse to get the right of exercising any control over female practitioners rather than say that they shall be submitted to the same control as the College exercises over its male licentiates.

Sir R. QUAIN did not see why the surplus population should seek to enter the College. Surely the Bar and the Church were more fitted for them. He fully concurred with what Dr. West, Sir J. Fayrer, Dr. Hare, and Dr. Powell had said, and he felt sure that the opinion of the College on the whole question would have great weight. He contended that in the interests of women themselves and of the public and the profession they should be discouraged from following medicine.

The PRESIDENT said that he had received a letter from Sir W. Jenner, in which he expressed the hope that none of these changes would take place, for he considered that women were unfit to enter the profession by their mental, moral, and physical conditions. His own opinion was much the same. He, too, did not think that women are physically, mentally, and morally fitted to become good medical practitioners. They may be able to pass examinations, to do many clever things, but they have not the knowledge of the world or powers to follow a profession of this exacting kind; nor was it good for the world that they should strive to follow it. He did not look at the question solely as regarded the College. His own judgment was against their entering the profession of medicine; it was the profession which of all they were the least qualified to follow. From a conversation he had lately with a gentleman who knew India well he could confirm what Sir J. Fayrer had said, that the physicians there had free access to all who were in need of their services.

A division was then taken, and there voted: *for* Dr. West's motion, 59; *against*, 50. The petition was thus rejected by a majority of nine votes.

The Comitia then adjourned.

The following is the petition of the students of the London School of Medicine for Women which gave rise to the preceding debate:—

TO THE REGISTRAR OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

"SIR,—We, the undersigned, desire respectfully to petition the Royal College of Physicians of London to admit to its examinations and diplomas students of the London School of Medicine for Women.

"A similar request was made many years ago to the Royal College of Surgeons, England, and refused; but we venture to hope for a different result upon the present occasion, when both Colleges will be approached. That request was made at a time when the admission of women to the medical profession was a question still *sub judice*. Doubts were then felt as to the effects which such a change would have upon the profession and upon women themselves. Years have since passed;

Digitized by Google

the main question has solved itself, and doubtful points have been settled by experience.

"At the beginning of the present year there were over 200 women upon the Medical Register, of whom more than 150 had been educated at the London School of Medicine for Women. One after another, universities and examining boards have admitted women to their degrees and diplomas, so that few now remain closed. In the charters of recently established universities the right of women to a degree is recognised. Several medical schools for women have been opened in Scotland and Ireland, and the total number of women studying medicine has steadily increased. Many women, both in this country and abroad, hold appointments on the staff of hospitals for women and children; some of these hospitals are worked entirely by women, and cases of all kinds and of all degrees of severity are received. Public bodies, like the General Post Office, the Metropolitan Asylums Board, and various county councils, have appointed women as assistant medical officers in the institutions under their control.

"The British Medical Association, the Medico-Psychological Association, the Society of Anæsthetists, and the Anatomical Society of Great Britain admit women as members. In short, the reception of women into the profession is going on steadily; and experience has proved that those evils have not resulted which it was feared might follow the admission of women to the study and practice of medicine, and that there is a demand for women as medical practitioners.

"The London School of Medicine for Women now numbers on its books 150 students. The results of its teaching, as shown by the position taken by its students in public examinations, are excellent. The biological, chemical, and physiological laboratories are adequate, though the Council desire to improve them, and are raising a fund for rebuilding the school. The Royal Free Hospital, to which students of the London School of Medicine for Woman alone are admitted, provides ample clinical opportunities, and the teaching of the staff is organised upon the usual lines.

"We, therefore, submit that the London School of Medicine for Women, with the Royal Free Hospital, is worthy of recognition by the Royal College of Physicians of London. The withholding of this recognition is a source of serious inconvenience and loss to the school and to its students. If desirous of taking a diploma from a college of physicians or surgeons the students are compelled to travel to Ireland or Scotland, and thus incur unnecessary expense and fatigue in connexion with their examinations.

"On the above grounds we earnestly hope that the Royal College of Physicians of London will accede to our petition, and will open its examinations to the students of the London School of Medicine for Women. We are, Sir, your obedient servants,

ELIZABETH GARRETT ANDERSON, M.D., Dean and Lecturer on Medicine.
JULIA COCK, M.D., Subdean.
ALFRED T. NORTON, F.R.C.S., Treasurer and Lecturer on Surgery.
ISABEL THORNE, Honorary Secretary.
Sir GAINSFORD BRUCE, Chairman of the Committee of the Royal Free Hospital.
CHARLES BURT, Chairman of the Weekly Board, Royal Free Hospital.
JOHN COCKLE, M.D., F.R.C.P., F.R.C.S., Consulting Physician.

"Royal Free Hospital Staff.

The following is the text of a statement circulated among the Fellows of the College prior to the meeting on Oct. 24th:—

"We the undersigned Fellows of the Royal College of Physicians of London, gravely impressed with the far-reaching importance of the question, now before the College, whether to admit women to its diplomas, desire to place on record our reasons against granting the prayer of the petition recently presented by the officers and teachers of the London School of Medicine for Women.

"In common with a large body of medical men—probably a great majority—we hold, and always have held, that the admission of women to the medical profession is most undesirable; and, whilst fully admitting the ability of women to comply with mere examinational tests, we are none the less convinced that they are by nature unfitted for the pursuit and practice of the medical profession.

"Although some holding this view have nevertheless deemed it both consistent and desirable not to oppose the admission of women, but have, on the contrary, given substantial aid to the attainment of that object, yet we see no reason to depart from our original carefully grounded objections, and, while recognising with regret the action of other bodies, desire to offer all legitimate opposition to the same course being followed by the Royal College of Physicians.

"We are unable to admit the force of the arguments urged in favour of the admission of women to the diplomas of the College, on the ground that other corporations and Universities have admitted them, and we fail to recognise any injustice in the refusal. The number of Universities and Medical Corporations of the United Kingdom which now admit women to their degrees or diplomas is sufficient to secure a full and complete trial of what at present is but an experiment—an experiment which another generation may show to be a mistake. In the metropolis itself the London University and the Apothecaries' Society open their doors to women, and thus offer ample opportunities for qualification.

"To the argument that the admission of women to the College is 'inevitable,' we desire to offer the fullest resistance; believing that the principle is wrong, we refuse to submit to considerations of expediency, and regard it as a duty which we owe to the College, to the Profession, and to the Public at large to prevent, to the utmost of our ability, the Royal College of Physicians being made a portal to the obtaining that which our reason and judgment condemn.

"On two points we have reason to believe considerable misconception exists. Inasmuch as the licence of the College gives a title to proceed to the membership, and that the Members are potential Fellows, it would be difficult if women were admitted to the lowest to exclude them from the higher diplomas. Those who support their admission must be prepared to admit them to the counsels and administration of the College, and to place the highest offices in the College within their reach.

"It is also urged that, in view of the possibility of the Royal College becoming associated for examinational purposes with a reconstituted London University, such a circumstance would of necessity compel the College to admit to its diplomas all candidates, irrespective of sex, in whose examination the College took a share. But this is not so. In all discussions in the College on the University question, the full power of the College to confer or withhold its diplomas by the vote of the Fellows, as at present (independently of the results of examination), has been fully reserved.

"On the ground, therefore, of our objection on principle to the admission of women to the profession, and having regard to the extensive opportunities they already possess for obtaining a registrable qualification, we protest against this College, the most ancient and influential medical corporation in the kingdom, being forced into a position from which there would be no receding and which could only be occupied with loss of dignity and prestige, in order to satisfy what we believe to be the improper demand of an inconsiderable minority.

"CHARLES WEST.	SAMUEL GEE.

"Oct. 22nd, 1895.

"*** The foregoing statement has only been prepared within the last few days, and no extended attempt has been made to obtain signatures. The College officers have not been asked to sign."

From the signatures attached to the petition and to the above circular it will be seen that a large number of Fellows of the College had publicly stated their views before the meeting. We have only to add that we consider it both a sign of the times and a manifestation of wisdom that the proceedings at the College on this occasion were not declared *secreta Collegii*.

THE YARROW CONVALESCENT HOME.

ON Saturday last, on the invitation of the beneficent founder, a very large party of medical men and others were conveyed by special train to Broadstairs, where every facility awaited them for seeing this Home (to the establishment of which we have already referred), with all its provisions for the comfort and the health of the young invalids and convalescents in the ranks of the respectable but straitened classes for whose benefit it has been erected. The day, though fine, was cold, but so admirably warmed was every corridor and room that everybody felt comfortable. The accommodation is for fifty girls and fifty boys under the age of fourteen, though there is power left to the committee,

Digitized by Google

in special circumstances, to admit those a year or two older. The five shillings a week that have to be paid are just enough to facilitate the selection of a class above the very poor, who are pretty well provided for in other homes. The building is of red brick and does credit to the architects and builders, respectively Messrs. Davis and Emanuel, Finsbury-circus, and Messrs. Colls and Sons, London. Every room is cheerful in its light and abundantly supplied with fresh air, which is warmed on its way into the house. This feature of warmth is very important and renders it possible to keep many cases in winter on a healthy coast which might otherwise be too cold. The walls of all the rooms are adorned with really pretty pictures, which are understood to be the gift of a friend of Mr. Yarrow. The Home stands in fine grounds covering an area of ten and a half acres, and has a fine sea frontage. The cost of the building and the endowment of it are the exclusive work of Mr. Yarrow, who admits no one to share in the pleasure, which he must feel to be great, of providing a convalescent home for classes that have been much overlooked by philanthropists. We have often thought, and even said, that this is the true way to found and endow hospitals in a wealthy country. It was thus that Guy's Hospital took its rise. It is an example to be followed.

Of two hundred guests that were present the great majority were members of the profession. Among them were Sir William Broadbent, Sir William Roberts, Sir J. Crichton Browne, the President of the Royal College of Surgeons of England (Mr. Heath), Mr. Hutchinson, Mr. Holmes, Mr. Langton, Mr. C. B. Keetley, Mr. Treves, Mr. Arbuthnot Lane, Mr. Reginald Harrison, Mr. Swinford Edwards, Dr. C. J. Hare, Dr. J. Harley, Dr. Stephen Mackenzie, Dr. J. B. Ball, Dr. Glover, Dr. Sainsbury, Dr. R. Dudfield, Mr. L. Bidwell, Mr. D'Arcy Power, Mr. Jackson Clarke, Dr. Stowers, Mr. Percy Dunn, Dr. Henderson, Mr. Charles King, Dr. Abercrombie, Mr. M. Morris, Dr. Alderson, Dr. Clemow, Mr. R. Lloyd, Mr. L. Mark, Mr. Jocelyn Swan, Dr. H. P. Henry, Dr. Clippingdale, Mr. H. Menzies, Dr. Eddowes, Dr. Yarrow, Dr. Lough, Mr. Lewis Lewis, Dr. Kisch, Dr. S. Smith, Mr. Mallam, Dr. Warham, Dr. Senior, Dr. Dodsworth, Mr. E. R. Spencer, and others.

Sir William Broadbent well represented the visitors, publicly thanking the founder for the Home as one likely to meet a great want. Mr. Yarrow's only anxiety is to be well advised of suitable cases, and for this he looks mainly to the medical profession. After the meeting on Saturday he is not likely to look in vain, and we heartily wish for the institution under the management of Miss Power a long career of usefulness.

REPORT OF THE MEDICAL OFFICER TO THE LOCAL GOVERNMENT BOARD, 1893-94.

[SECOND NOTICE.[1]]

CONTINUING our analysis of the contents of this publication, we have to notice a report by Dr. Wheaton on an outbreak of diphtheria in the Hinckley urban and rura sanitary districts. The precise extent of this outbreak, which occurred from September to November, 1893, is not accurately known, as notification is not in operation in the district. However, the fact that within eleven weeks there occurred no fewer than twenty-eight deaths from this disease, as compared with but one such death in the preceding eight months, points to an epidemic of considerable proportions, probably between two and three hundred attacks. The inquiry was conducted carefully and systematically, with the result that neither the water-supply, milk-supply, nor general sanitary conditions could be implicated as the cause of the outbreak. The cases were fairly equally distributed, and no connexion could be traced between their incidence and local drainage or other defects; indeed, the majority of cases occurred in houses where the drains were in good condition. On the other hand Dr. Wheaton believes that the susceptibility to infection and the severity of attacks are probably influenced by exposure to the effluvia from privy middens and the impregnation of the surrounding soil. The precise origin of the outbreak is a matter of doubt. There had been a large fair in the town at the end of August, whilst ever since the previous year "septic" throats had prevailed in association with measles or scarlet fever. But if the origin of the outbreak was mysterious there can be no doubt as to the influence of schools in spreading the disease. The outbreak coincided with the reopening of the schools, and the families attacked were almost exclusively those whose children attended the public elementary schools. The incidence of the disease was mainly on children under fourteen years of age, and in nearly every one of these the first to be attacked was attending one or other of the schools. When to this is added the lack of sufficient sanitary precautions, of disinfection and the like, the spread through the school attendance of children from infected houses accounts for a great deal of the epidemic. Dr. Wheaton found that sore-throats were exceedingly common among the school children, and he himself met with several cases among the children of the town generally, including those who were below school age. The relationship of these forms of sore-throat to diphtheria is discussed, and the inference to be drawn is that this must be very close. It is remarkable that these throat affections undoubtedly prevailed most in insanitary houses with defective drains, ill-constructed middens, and the like. The bacteriology of these forms of sore-throat is a subject which is worthy of elucidation, and its study may throw some light on their alliance with diphtheria.

The remarkable outbreaks of a form of Epidemic Skin Disease amongst the inmates of certain metropolitan workhouse infirmaries, to which attention was first directed in 1891 by Dr. Savill at Paddington and Marylebone infirmaries, forms the subject of a lengthy report by Dr. Monckton Copeman. His inquiry related to the outbreaks in 1893 and 1894 at the infirmaries of Bethnal Green, Bow, Shoreditch, St. Marylebone, and St. George's-in-the-East. The clinical and pathological characters of the affection are lucidly described, their resemblance to pityriasis rubra and acute general eczema pointed out, and the fact that this was associated with marked febrile disturbance, the eruption being followed by great desquamation and not infrequent relapse. The fatality was from 5 to 12 per cent. of the attacks, the fatal cases being generally in the aged, and in some preceded by albuminuria and uræmia. It can hardly be said that the etiology of this peculiar affection has been fully cleared up. The subjects were all fairly advanced in years and of both sexes, and being infirmary subjects were mostly suffering from chronic ailments. The disease could not be attributed to any ordinary sanitary defects, although it is stated—as may naturally be expected—that lack of ventilation seemed to be responsible for its spread and for the severity of attack. In one instance it seemed as if the milk-supply had to do with the outbreak, but in another infirmary there was no reason to suspect that this article of diet had any such relationship with the disease. Nevertheless, in the former instance there was so marked a coincidence between the first occurrence of the affection and a change in the supply of milk, and a similar coincidence between other outbreaks and the milk-supply from the same contractor, that it is difficult to altogether set aside the hypothesis. Dr. Copeman and Dr. F. W. Andrewes made bacteriological investigations into the disease, but they failed to detect any specific organism other than a staphylococcus identical with one that is known to occur in healthy skin. The report is furnished with several portraits and with clinical charts.

The important subject of Lead Poisoning from the consumption of Water derived from certain Moorlands has been for several years under consideration. In 1885 Dr. Sinclair White, then medical officer of health of Sheffield, had reported that the implicated waters had an acid reaction, and in a communication to the Local Government Board upon this report Mr. W. H. Power had suggested that the special quality of such water which rendered it capable of dissolving lead might possibly be due to the agency of a microphyte. It was then decided to make an exhaustive inquiry into the prevalence of lead poisoning amongst the consumers of moorland waters and to determine more precisely the conditions under which the water acquires this property. An interim report on the inquiry is here published from Mr. Power's pen. The investigation began in 1890 and is not yet completed. It was determined to study these waters on their gathering grounds, and for this purpose the laboratory work was carried on at Settle, first by Mr. and Mrs. Atkinson of Settle, under the supervision of Dr. Barry, and later by Dr. Houston. An extensive preliminary inquiry had shown that, whereas in the West Riding lead poisoning

[1] The First Notice was published in THE LANCET of Sept. 28th, 1895.

Digitized by Google

attributed to moorland water was widely recognised, it was hardly known in districts of Lancashire, and not at all in Cumberland and Westmorland. The report (page 335) says: "How far this contrast in the amount of observed lead poisoning in the several counties was to be thought of as referable to intrinsic differences in moorland water as such, to precautionary measures, private or public, that had been taken, or to want of recognition of lead poisoning that was tending to occur could not be judged of from the data supplied, so that it was seen that in these aspects the subject would require further study, which has accordingly been undertaken."

The Settle investigations had, prior to Dr. Houston assuming their direction, established the fact that not only was the solubility of lead associated with acidity of the water, but that no other condition was implicated, the research being carried on with a particular water, of which samples were gathered and examined regularly week by week for a long period (the specimens of water were taken from Burnmoor from November, 1891, to April, 1893). The continuous labour involved in these investigations must have been considerable; their result is concisely summarised by Mr. Power as follows (page 338): "As the outcome, therefore, of exact study of the natural history of different classes of waters from the given gathering ground, one class alone of such waters—that obtained from certain pools in the peat—was found to possess in marked degree, and persistently, ability to dissolve lead. And, further, among a plurality of conditions, physical and chemical, appertaining to this particular class of water, one alone was found distinctly and uniformly parallel to its property of readily dissolving lead—namely, acidity of nearly every sample."

To Dr. Houston has been assigned the task of extending these observations in the direction of determining the differences in action on lead exercised by water, and the correlation of acidity and lead-dissolving property in regard of moorland waters. More important still has been the attempt to determine the cause of the acidity of moorland water. This work is still in progress, but it suffices here to state that he has succeeded in finding an intimate connexion between the development of acidity and the presence of certain bacterial organisms derived from peat, the morphological and biological characters of which are described in an appendix to the report. Thus it will be seen that there is every probability that Mr. Power's sagacious inference from his study of the facts of the Sheffield observations in 1885 is likely to be verified, and a way found of depriving moorland water of this obnoxious quality.

A report on Cholera in Germany during the winter of 1892-93, by Dr. F. W. Barry, and a memorandum on the sanitary survey of the ports and riparian sanitary districts made by the officers of the Board during 1893, as well as the various memoranda issued on the subject of cholera by the medical officer, keep this important question fully under notice. Dr. Thorne Thorne also makes a report with his colleagues of the British delegation upon the International Sanitary Conference of Dresden.

The space devoted to the record of scientific investigations undertaken for the department during the year is not so large as usual, but the interest of the reports contained in this part is in no way inferior. Dr. Klein, continuing his studies on the Etiology of Typhoid Fever, shows that the differentiation between the typhoid fever bacillus and the bacillus coli (considered to be identical by some French authorities) obtains outside the animal body in water. He proposes to further study the behaviour of these two organisms in waters of various characters and under various conditions. In his examination of the water furnished by the supplies at Worthing and at Rotherham during the epidemics in those places he found true bacillus coli, as well as a bacillus closely resembling it, and in a few colonies a bacillus presenting the characters of the typhoid fever organism. Dr. Klein also carried out a series of experiments upon monkeys, both by feeding and inoculation, with the typhoid fever bacillus without obtaining any evidence of the lesions of that disease in the animals, except that in the latter group (inoculations) some presented splenic enlargement and one had also enlargement of lymphatic glands. Nor were the results of bacteriological examination more conclusive, and, as Dr. Thorne Thorne says, they were too indefinite for Dr. Klein's purpose. He next proceeded to inoculate calves subcutaneously with cultures of the typhoid fever bacillus; no febrile disturbance followed, but the lymphatic glands of the inoculated region were swollen and yielded the typhoid fever bacillus "in abundance." It remains to be seen whether this organism can multiply in the tissues of the milch cow, and, if so, "if it is at any time capable of passing out of the animal's body by way of the milk gland or milk," and this Dr. Klein proposes to investigate. The same observer contributes a further Report of his researches on the Antagonisms of Microbes, in which he shows that no poisonous action is exerted by intra-peritoneal injections in guinea-pigs of large doses of the intra-cellular substance of bacillus anthracis, of bacillus diphtheriæ, and of bacillus of fowl cholera respectively, which therein differ from Koch's cholera vibrio, Finkler's vibrio, the bacillus coli, the typhoid fever bacillus, the bacillus prodigiosus, and the proteus vulgaris. Nor does such injection (in the case of the three first-named) "confer any immunity whatever against, or any tolerance of, a further injection with the living microbes." The bacillus of grouse disease, however, resembles the second group in the protection conferred by injection of its intra-cellular substance into the guinea-pig. Dr. Klein also reports on Psorosperms in their Relation to the Etiology of Cancer in a paper largely critical of the work done by other observers on this subject, concluding that the intra-cellular bodies alleged to be parasitic in nature are to be explained by nuclear and other changes. He excludes, however, from this category the amœba-like bodies discovered by Kerotneff and named by him "rhophalocephalus carcinomatosus," but even these are sparse in distribution and may have no etiological relationship with the cell proliferation of carcinoma. Some further research on the Etiology of Vaccinia is also reported by Dr. Klein. It consists mainly in the record of failure to cultivate vaccine lymph either directly on culture media or indirectly by using the tissue of glands enlarged after inoculation of the guinea-pig or calf with vaccine lymph.

Dr. Sidney Martin gives a preliminary report of his investigations upon the Chemical Pathology of Tetanus, his general conclusions as so far obtained being: "(1) That in all cases of traumatic tetanus there are present, in the spleen and in the blood, the products of bacterial action—viz., albumoses, and certain acid organic bodies; (2) that to the albumoses must be ascribed the production of the fever of tetanus—they produce no tetanic convulsions; and (3) that the other extract contains the substances which are the direct excitants of the muscular spasms in tetanus."

The volume concludes with a paper by Dr. Cautley on the Bacteriology of Catarrh, the nasal secretions being examined in ten cases, which, although yielding several microbes, did not contain any to which specific characters could be attributed; and also papers by the same observer on the Micro-organisms found in the Bronchial and in the Mesenteric Glands.

THE CASE OF MR. R. B. ANDERSON.

FROM time to time we have recorded the various stages reached in this case, and quite recently [1] we gave a *résumé* of the whole case. It will be remembered that the jury who tried Mr. Anderson's case in England returned a verdict in his favour, but the presiding judge entered judgment for the defendant on the ground that no action would lie against a judge in his judicial capacity. This judgment was upheld on appeal. Mr. Anderson gave notice to set aside this judgment, but the Court ordered it to be struck out of the list. He then served a notice of motion to have the original motion restored, and on Thursday, Oct. 24th, personally applied to the Court for leave to have this motion heard, and that the judgment should be set aside as void or voidable on the ground that, since the judgment had been given, he had discovered certain new facts which, he alleged, disqualified Lord Esher, one of the judges constituting the Court of Appeal, from taking part in the judgment. As Lord Esher was sitting on the bench now, Mr. Anderson applied that the Court should be properly constituted, stating that he had authorities to show that the Court had power to set aside its own judgments, and explaining that, as an action was pending against Lord Esher at the time an appeal was made, the Court which heard the case was not properly constituted and the judgment not a judgment at all. The Court, however, dismissed the application.

Mr. Anderson, we understand, will now take the case to

[1] THE LANCET, Aug. 31st, 1895.

Digitized by Google

the House of Lords, providing he is not deterred by the consequent expenses. But, surely, Englishmen, who in times past have fought some noble battles for their rights in cases almost as hopeless as this appears to be, will not withhold the sinews of war for a cause which concerns themselves as much as it does Mr. Anderson. The justness of his cause has been recognised by law, but because his oppressor is one who had the right to administer the law Mr. Anderson is compelled to go without redress.

The Civil Rights Defence Committee, whose address is 5, Mitre-court, Temple, have charge of the case, and we wish them God-speed in their efforts.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

Wolverhampton Urban Sanitary District.—The county borough of Wolverhampton, one of the thirty-three great towns, had during 1894 a corrected death-rate of 21·66 per 1000, as against an average for the thirty-three towns of 19·59. Its zymotic death-rate (3·23 per 1000) was, too, above the large towns average, which was 2·24. In the matter of scarlet fever mortality Wolverhampton takes first place with a rate of 0·63 per 1000, against an average of 0·21. The social conditions appertaining to the east sub-district of the borough are, Dr. Henry Malet considers, very largely responsible for the high death-rate of Wolverhampton. As an instance of the protective value of vaccination to persons exposed to small-pox Dr. Malet gives the following table showing the number of vaccinated, unvaccinated, and re-vaccinated exposed in infected houses and the protection afforded in each case:—

—	Persons.	Cases of small-pox.	Deaths.	Very severe.	Severe.	Mild.	Very mild.
Vaccinated	241	54	3	2	4	6	39
Unvaccinated	21	8	2	3	3	—	—
Revaccinated	10	—	—	—	—	—	—

To the ten revaccinated persons referred to in the table may be added thirteen members of the staff, all of whom remained exempt from attack. In dealing with the question of scarlet fever Dr. Malet alludes to the much higher fatality-rate which characterised the cases occurring in the east sub-district as compared with those in the west, the difference being equally marked both in home treated and hospital treated cases. A certain number of enteric fever cases which occurred in Wolverhampton during 1894 may possibly have been due to the consumption of infected watercress; while a small outburst of scarlet fever was brought home to milk infected with that disease. Dr. Malet makes some interesting observations on "return" cases of scarlet fever, a subject which we notice is to be discussed at the Epidemiological Society on Nov. 15th by Mr. T. W. Thompson, the author of that admirable monograph on the Natural History of Infectious Diseases contained in vol. ii. of Stevenson and Murphy's "Treatise on Hygiene and Public Health."

Dumbarton County Sanitary District.—In his annual report for 1894 Dr. J. C. McVail sets before his sanitary authority the general principles which should be held in view with regard to the formation of special scavenging and cleansing districts according to the provisions of the Local Government (Scotland) Act, 1894. From the scavenging facilities afforded by the Act Dr. McVail anticipates very great benefit, and he points to the danger which must necessarily accrue from the present air pollution caused by "heaps of decomposing filth collected behind almost every house." Dr. McVail records some interesting outbreaks of infectious disease in his report. In one instance a local outbreak of enteric fever may have had its origin either in a polluted water-supply or in manure from Glasgow. Under either circumstances there would appear to be need of reform; the water should be protected from risks of pollution, and the manure traffic should be so carried on as to diminish the nuisance as much as possible; covered sheds should be used for unloading, as Dr. McVail advises, and covered carts and waggons for transport. A peculiar outbreak of diarrhœa occurred at Woodilee Asylum during 1894. The first few cases were all in one ward, and several cases occurred in adjoining beds. There were three deaths. Drainage, food, milk, and apparently water were excluded as causes of the outbreak. On the whole, Dr. McVail was inclined to regard this disease as an irritative diarrhœa capable of conveyance atmospherically from bed to bed or by nursing, cooking utensils, or night-stools. Once developed, it manifested an ability to attack able-bodied individuals, such as nurses and others exposed to contagion; in fact, the outbreak seems to have borne some resemblance to that which occurred at Greenwich Workhouse in 1893. Into the question of rivers pollution Dr. McVail does not enter in his annual report, as the subject is to be dealt with in special reports, one of which, that relating to the Gareloch, is noticed below.

Bolton Urban Sanitary District.—The estimated population of Bolton for 1894 was 118,303, and the number of persons to an acre 50·2. The fall which has taken place in the general death-rate of this district since 1851 is one which should encourage the sanitary authority. For the four decades comprised within the years 1851 to 1890 the average rates per 1000 were respectively 30·7, 27·5, 23·8, and 21·8; per 1000 for the four years 1891–94 the average rate was 21·7, and for the year 1894 18·7.

ESTUARY POLLUTION IN DUMBARTONSHIRE.

In his annual report for 1894 Dr. J. C. McVail, the medical officer of health for the county of Dumbarton, omitted any detailed reference to rivers pollution in his district owing to the fact that the subject was about to be dealt with in special reports. The first of these reports, that referring to the pollution of the Gareloch, has just reached us, and it is certainly an extremely interesting document. The Gareloch is a branch of the Clyde estuary, and as such the Rivers Pollution (Prevention) Act does not apply to it without an Order from the Secretary for Scotland. The waters of this arm of the Clyde are much polluted by human excrement, and with a view to the discontinuance of such pollution an endeavour is being made by the Dumbarton County Council to bring the Gareloch under the operations of the Rivers Pollution (Prevention) Act. As a means to this end an elaborate report has been made to the Rivers Pollution Committee of the Council by Mr. Francis Buchanan, convener of the Public Health Committee, and Dr. McVail. The inquiry relates solely to the pollution of the Gareloch, and it has been deemed advisable to confine the inquiry to the drainage of the dwelling-houses on the shore of the loch and pollutions of the vessels anchored in, or plying on, its waters. The effects of the pollutions of the Clyde upon the condition of the Gareloch have not been dealt with. In order to establish the degree and effect of the pollutions experiments were made in regard to the currents in the loch and to the amount of suspended fæcal matter present. The observations with respect to the currents were made with heavy wooden floats sunk well into the water by means of a leaden keel, and kept in view by means of a flag; it was found that cork floats were too much influenced by the wind to give a correct idea of the currents. The results of the float experiments were very interesting, as they showed that excreta from ships in the loch tend to be carried up and down its waters rather than to pass out into the Clyde. The observations with regard to the matter in suspension were made with tow-nets consisting of bags constructed of fine but strong muslin which were towed behind a steam launch. By this means much fæcal matter was collected, and it was demonstrated that one of the chief causes of pollution in the outer basin was due to the *Empress* training ship, with some 400 persons on board, which was anchored in this locality. These interesting observations were made by Mr. Pearcy of Owens College, Manchester, who had experience of this sort in the *Challenger* expedition, and the same gentleman also makes in the report some very interesting observations on the influence of pollutions upon marine life. That there is considerable pollution of the Gareloch has certainly been demonstrated, and the question now is as to whether the Secretary for Scotland will consider the facts adduced sufficient to justify him in

Digitized by Google

bringing the Gareloch under the provisions of the Rivers Pollution Act, or sanctioning by-laws under Section 57 of the Local Government Act, 1889. The question is one of very considerable public importance, as doubtless other sanitary authorities, both in Scotland and England, cannot fail to be guided in some degree in their future action by the decision of the Secretary for Scotland.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns 6111 births and 4011 deaths were registered during the week ending Oct. 26th. The annual rate of mortality in these towns, which had been 21·0 and 19·1 per 1000 in the two preceding weeks, rose again to 19·7 last week. In London the rate was 17·5 per 1000, while it averaged 21·4 in the thirty-two provincial towns. The lowest rates in these towns were 12·7 in Croydon, 13·1 in Huddersfield, 13·5 in Brighton, 15·5 in Bristol, and 15·9 in Leicester; the highest rates were 27·6 in Sunderland, 27·7 in Burnley, 27·8 in Liverpool, 30·5 in Salford, and 32·3 in Blackburn. The 4011 deaths included 583 which were referred to the principal zymotic diseases, against 895 and 670 in the two preceding weeks; of these, 203 resulted from diarrhœa, 121 from measles, 95 from diphtheria, 74 from "fever" (principally enteric), 47 from whooping-cough, 42 from scarlet fever, and 1 from small-pox. No fatal case of any of these diseases was registered last week in Derby; in the other towns they caused the lowest death-rates in Brighton, Portsmouth, Plymouth, and Nottingham, and the highest rates in Oldham, Swansea, Burnley, and Blackburn. The greatest mortality from measles occurred in Salford, Oldham, Swansea, and Blackburn; from whooping-cough in Wolverhampton; from "fever" in Oldham, Burnley, Bolton, and Sunderland; and from diarrhœa in Manchester, Swansea, Blackburn, and Burnley. The 95 deaths from diphtheria included 61 in London, 8 in West Ham, 4 in Birmingham, 3 in Cardiff, and 3 in Wolverhampton. One fatal case of small-pox was registered in London, but not one in any other of the thirty-three large towns. There were 114 cases of small-pox under treatment in the Metropolitan Asylum Hospitals and in the Highgate Small-pox Hospital on Saturday last, the 26th ult., against 198, 158, and 119 at the end of the three preceding weeks; 14 new cases were admitted during the week, against 17, 9, and 7 in the three preceding weeks. The number of scarlet fever patients in the Metropolitan Asylum Hospitals and in the London Fever Hospital at the end of the week was 2833, against 2802, 2827, and 2838 on the three preceding Saturdays; 269 new cases were admitted during the week, against 252, 332, and 241 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 158, 175, and 215 in the three preceding weeks, further rose to 235 last week, but were 137 below the corrected average. The causes of 57, or 1·4 per cent., of the deaths in the thirty-three towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Portsmouth, Cardiff, Bradford, Newcastle-on-Tyne, and in twelve other smaller towns; the largest proportions of uncertified deaths were registered in West Ham, Birmingham, Leicester, Liverpool, and Hull.

HEALTH OF SCOTCH TOWNS.
